## ABSTRACT

In this work the thermal diffusion behavior of micellar systems and microemulsions is studied. These model systems are used to investigate two open questions. The first question focuses on the influence of the micelle formation around the critical micelle concentration (*cmc*) on the thermal diffusion behavior. In order to answer this, we studied the thermal diffusion behavior of the nonionic surfactant *n*-Octyl  $\beta$ -D-glucopyranoside ( $C_8G_1$ ) in water, which shows a fairly high *cmc* at 0.65 wt% for different concentrations between  $w = 0.25$  wt% and  $w = 2.0$  wt% in a temperature range from  $T = 15$  °C to 60 °C using the classical and infrared thermal diffusion forced Rayleigh scattering (*TDFRS*) setup. The *cmc* is independently determined by surface tension measurements. In classical TD-FRS experiments, the surfactant solutions show, in the presence of a light-absorbing dye, a pronounced change of the thermal diffusion coefficient,  $D_T$ , and the Soret coefficient,  $S_T$ , at the *cmc*. This result agrees with a recent thermal lens study [Santos *et al.*, Phys. Rev. E 2008, **77**, 011403], which showed, also in the presence of dye, a pronounced change of the matter part of the thermal lens signal around the *cmc*. We found that the change in the thermal diffusion properties becomes less pronounced if the dye is absent or a light source is used which is not absorbed by the dye. At higher concentrations, we observed a temperature-dependent sign inversion of  $S_T$  as has also been found for solutions of hard spheres at higher concentrations. We also studied the sugar surfactants *n*-Heptyl  $\beta$ -D-glucopyranoside ( $C_7G_1$ ) and *n*-Octyl  $\beta$ -D-maltopyranoside ( $C_8G_2$ ), to investigate the influence of the number of head groups and the length of the alkyl chain on the thermal diffusion behavior. In the low concentration regime around the *cmc*, the abrupt change of  $S_T$  was confirmed for  $C_7G_1$  and  $C_8G_2$ . Further, the sign change in the high concentration regime was confirmed. The second question is the radial dependence of the Soret coefficient. It is controversially discussed whether the radial dependence of  $S_T$  is quadratic

or linear. We shed some light on this discussion by investigating microemulsions which are used as a model system of spherical particles. This thermodynamically stable and nanostructured ternary system of water, oil, and surfactant forms in the one phase ( $1\phi$ ) region of the phase diagram oil-in-water ( $o/w$ ) at the water-rich side or water-in-oil ( $w/o$ ) microemulsion droplets at the oil-rich side, respectively. Size and shape of these droplets can be tuned by varying temperature or concentration without changing the chemistry of the droplet. We studied the microemulsion  $H_2O/n$ -alkane/pentaethylene glycol monododecyl ether close to the emulsification failure boundary ( $efb$ ) to ensure a spherical shape of the microemulsion droplets. Due to the temperature dependence of the  $efb$ , not only the size but simultaneously the temperature changes if one considers the microemulsion droplets along the  $efb$ . Therefore, the  $n$ -alkane was varied in order to make sure that the temperature is the same for all droplets of different sizes. The hydrodynamic radius of the investigated samples varied between 4.72 nm ( $n$ -tetradecane) and 15.20 nm ( $n$ -octane). Simultaneously also the droplet volume fraction changed from 4.76 vol% ( $n$ -tetradecane) to 10.50 vol% ( $n$ -octane). For all  $n$ -alkane systems, small angle neutron scattering ( $SANS$ ) experiments were performed to verify the spherical structure of the droplets. The analysis of the Soret coefficient of these different microemulsion systems leads to a rather linear size dependence of the droplets on the water-rich side. Preliminary measurements show the same trend for the oil-rich side.

## KURZZUSAMMENFASSUNG

In dieser Arbeit haben wir das Thermodiffusionsverhalten von mizellaren Systemen und Mikroemulsionen untersucht. Beide Systeme werden als Modellsysteme genutzt um zwei Fragestellungen zu beantworten. Die erste Fragestellung bezieht sich auf den Einfluss der Mizellenbildung nahe der kritischen Mizellenkonzentration (*cmc*) auf das Thermodiffusionsverhalten. Dazu untersuchen wir das Thermodiffusionsverhalten des nichtionischen Tensides *n*-Octyl  $\beta$ -D-glucopyranoside ( $C_8G_1$ ) in Wasser, welches eine relativ hohe *cmc* bei 0.65 wt% besitzt, im Konzentrationsbereich zwischen  $w = 0.25$  wt% und  $w = 2.0$  wt% und im Temperaturbereich von  $T = 15$  °C bis 60 °C in der klassischen und infraroten *thermal diffusion forced Rayleigh scattering* (TDFRS) Anlage. Zudem haben wir unabhängig von den TDFRS Messungen die kritische Mizellenkonzentration durch Oberflächenspannungsmessungen bestimmt. In der klassischen TDFRS Anlage zeigt das Tensidsystem unter Einfluss eines lichtabsorbierenden Farbstoffes eine ausgeprägte Veränderung des Thermodiffusionskoeffizienten,  $D_T$ , und des Soret Koeffizienten,  $S_T$ , in der Nähe der *cmc*. Dieses Ergebnis weist in die gleiche Richtung wie eine kürzlich veröffentlichte Arbeit von Santos *et al.* [Phys. Rev. E 2008, **77**, 011403], in der unter Farbstoffeinfluss ebenfalls eine deutliche Änderung des Messsignals in einem thermischen Linsenexperiment bei der *cmc* beobachtet wurde. Wir fanden zudem heraus, dass die Änderung des Thermodiffusionskoeffizienten, sowohl ohne Farbstoff als auch wenn die Laserwellenlänge des Schreiblasers nicht durch den Farbstoff absorbiert wird, weniger stark ausgeprägt ist. Bei höheren Konzentrationen konnten wir einen temperaturabhängigen Vorzeichenwechsel des Soret Koeffizienten beobachten. Desweiteren haben wir untersucht, ob strukturelle Änderungen, wie die Zahl der Kopfgruppen oder die Länge der Alkylketten einen Einfluss auf das Thermodiffusionsverhalten haben. Messungen an *n*-Heptyl  $\beta$ -D-glucopyranoside ( $C_7G_1$ ) und an *n*-Octyl  $\beta$ -D-maltopyranoside ( $C_8G_2$ ) zeigten ebenfalls eine signifikante

Änderung der Thermodiffusionskoeffizienten an der *cmc*. Im höheren Konzentrationsbereich konnten wir nicht nur den  $S_T$ -Vorzeichenwechsel bestätigen, sondern durch Skalierung der Konzentration und des Soret Koeffizienten eine Masterkurve erhalten. Die zweite Fragestellung dieser Arbeit betrifft die Bestimmung der radialen Abhängigkeit des Soret Koeffizienten für den bislang experimentell sowohl eine lineare als auch eine quadratische Größenabhängigkeit gefunden wurde. Wir haben diese Fragestellung mithilfe von Mikroemulsionen untersucht, die wir als Modellsystem für sphärische Teilchen benutzt haben. Mikroemulsionen sind thermodynamisch stabile, nanoskopisch strukturierte, ternäre Systeme aus Wasser, Öl und Tensid. Mikroemulsionen formen in den  $1\phi$ -Regionen des Phasendiagramms auf der wasser- bzw. ölreichen Seite o/w bzw. w/o Tröpfchen. Größe und Form dieser Tröpfchen lassen sich über Temperatur-, Konzentrationsvariationen oder Zusammensetzung der Komponenten einstellen ohne dass sich die Chemie der Mikroemulsionströpfchen ändert. Wir untersuchen  $H_2O/n$ -Alkan/Pentaethylene glycol monododecyl ether Mikroemulsionen nahe der unteren Entmischungsgrenze des Einphasengebietes auf der wasserreichen Seite, der sogenannten *emulsification failure boundary* (*efb*), an der die Mikroemulsionströpfchen kugelförmig sind. Wenn man die Größe der Tröpfchen ändert indem man sich entlang der *efb* bewegt, verändert sich gleichzeitig auch die Temperatur. Deswegen wurde die Kettenlänge des  $n$ -Alkanes variiert um Tröpfchen unterschiedlicher Größe bei gleicher Temperatur zu studieren. Die untersuchten Mikroemulsionen decken einen Tröpfchenradius von 4.72 nm ( $n$ -Tetradecan) bis 15.20 nm ( $n$ -Octan) ab. Allerdings ändert sich dabei der Volumenbruch der Tröpfchen zwischen 4.76 vol% ( $n$ -Tetradecan) und 10.50 vol% ( $n$ -Octan). Für alle untersuchten Mikroemulsionen wurden Form, Größe und Wechselwirkungseffekte der Tröpfchen mit Neutronenstreuung charakterisiert. Die Messungen auf der wasserreichen Seite ergaben eine lineare Abhängigkeit des Soret Koeffizienten vom Radius der Tröpfchen. Erste Messungen auf der ölreichen Seite bestätigen dieses Ergebnis.

## INTRODUCTION

The effect of thermodiffusion describes mass separation in a mixture due to a temperature gradient. This effect is also called Ludwig-Soret-Effect denoted after the discoverers Carl Ludwig [1] and Charles Soret [2–4]. Thermodiffusion became not only important for the separation of crude oils [5] and isotopes [6–8] but plays also a role in biological systems or terrestrial cycles [9–11]. Since its discovery, many experimental methods have been developed. In those early days a quantitative determination of the thermal diffusion coefficient was often not possible due to interference with convection. First systematic studies have been performed in a thermal diffusion column [12] for gaseous systems and also for liquid mixtures [13]. Several experimental techniques have been developed, for instance the Soret cell [14, 15], the laser beam deflection technique [16, 17], the thermal lens method [18], the thermal flow field fractionation [19, 20], a fluorescence method [21] or the thermal diffusion forced Rayleigh scattering technique [22–25].

The strength of the concentration gradient caused by a temperature gradient due to thermal diffusion in the steady state is described by the Soret coefficient,  $S_T$ :

$$S_T = -\frac{1}{w(1-w)} \cdot \frac{\Delta w}{\Delta T} = \frac{D_T}{D} \quad (1.1)$$

with the resulting difference in concentration,  $\Delta w$ , due to an applied temperature difference,  $\Delta T$ . Eq.1.1 also introduces the Soret coefficient as the ratio of the mass diffusion coefficient,  $D$ , and the thermal diffusion coefficient,  $D_T$ .

The first theory, which predicted the thermal diffusion effect for gas mixtures, was the

kinetic gas theory by Chapman and Enskog [26, 27]. All attempts to expand their theory for dense and interacting systems, such as liquids, failed. Although theoretical approaches are able to describe the thermal diffusion behavior of selected systems [28–32], a general description of the Soret effect on a molecular level is still lacking.

Experimentally, many systematic measurements of the thermal diffusion properties of low-molecular weight mixtures, micellar systems of ionic [33–37] and nonionic amphiphiles [38–41], polymers and colloidal suspensions have been performed [21, 42–50] in order to build a reliable database to evaluate theories and simulations. The advantage of low-molecular weight mixtures is that they are accessible by molecular dynamic simulations [51–54]. For polymeric systems power laws as function of the chain length can be derived [31, 32]. The advantage of colloidal model systems is that they can be used as large atomic model systems for which interaction strength and size can be tuned [30, 55–57] and which can be described by analytical theories.

Although there is no full microscopic understanding for the thermal diffusion process, some correlations between certain physical and chemical properties and the Soret or thermal diffusion coefficient can be found. Often, the heavier molecules, the larger molecules, the molecules with the higher symmetry tend to accumulate in the cold region. But there are also exceptions from the rule of thumb which are often related with specific chemical interactions such as hydrogen bonds or changes in the solvent quality [31, 32, 42, 51, 58–62].

In this work we want to use micellar and microemulsions as model systems to shed some light on two open questions. The first question is related to the influence of the micelle formation on the thermal diffusion behavior around the critical micelle concentration, while the second question points to the radial dependence of the Soret coefficient, which should be investigated using microemulsions.

Monomerically dissolved amphiphilic surfactant molecules are regarded as a self-assembling system as they form micelles at a critical micelle concentration ( $cmc$ ). Santos *et al.* [34] recently investigated the thermal diffusion behavior of potassium laurate in water in the vicinity of the  $cmc$  and found an abrupt change of the matter part of a thermal lens signal at the  $cmc$ . Unfortunately, an evaluation of  $S_T$  was not possible due to the presence of a dye which complicated the analysis. Therefore, it remained unclear to which extent the  $cmc$  is also visible in the thermal diffusion or Soret coefficient. To clarify these observations, the thermal diffusion behavior of micellar systems with a high  $cmc$  needs to be investigated without the addition of dye. Among the wide range of

---

surfactants, we chose a nonionic sugar surfactant with a fairly high  $cmc$  such as  $n$ -Octyl  $\beta$ -D-glucopyranoside.

For a system consisting of amphiphilic surfactants, unfavored solvent-solute interactions cause the formation of micelles and are thereon the reason for the existence of the  $cmc$ . Additionally, these interactions and in general changes in the solvent quality induce also a sign change of the Soret coefficient. This sign change behavior is a common observation, which has already been found for many different organic [59, 62, 63], aqueous [48, 64] or charged [33] mixtures. It is one topic of this work to investigate the occurrence of a sign change behavior of the Soret coefficient in sugar surfactant solutions. Beside the concentration dependence also the temperature dependence, which has been described by an empirical equation suggested by Iacopini *et al.* [64], can be studied.

Recent studies have been performed in a thermal diffusion forced Rayleigh scattering (TDFRS) setup. With this experimental method, only small temperature gradients in the order of 20 – 100  $\mu$ K are applied, so that for instance microemulsion systems will not undergo a phase transition. Another advantage of the experimental method is that the fringe spacing between the warm and the cold is in the order of only 20  $\mu$ m, which allows short equilibration times of only a few seconds and avoids convection. In some TDFRS setups, this temperature gradient can only be induced in the presence of dye. Unfortunately, studies with the classical TDFRS setup in the presence of a light absorbing dye showed a pronounced change of the thermal diffusion and the Soret coefficient [38]. But this change is less distinct, if the dye is absent or a light source is used, which is not absorbed by the dye [58].

The radial dependence of the Soret coefficient is an open question. Some experimental studies found a quadratic [65], others a linear [35, 66, 67] relation. While Duhr and Braun [65] observed an unambiguous quadratic radial dependence of  $S_T$  for carboxyl modified polystyrene (PS) beads in 1 mM TRIS buffer of different radii in the range from 20 nm to 1000 nm using a microscopic fluorescence technique, studies by Putnam and Cahill [67] of carboxyl functionalized PS spheres in a size range from 26 nm to 92 nm in diameter gave some indication that the behavior could also be linear. Additionally, Vigolo *et al.* [35] obtained a linear dependence investigating AOT/isooctane/water microemulsion droplets with a radius between 1.8 nm and 16 nm. Unfortunately, the shape of these microemulsion droplets has not yet systematically been characterized by neutron scattering methods, so that it is not sure that the microemulsion droplets are spherical in the investigated range. Another complication of this system is, that simultaneously with a radial change also the

surface charge density will decrease with increasing radius. This will alter the electrostatic contribution to the thermal diffusion properties, so that the obtained radial dependence is not solely determined by a size change. Recently, Braibanti *et al.* [66] repeated the experiment of Duhr and Braun [65] and studied also the thermal diffusion behavior of highly diluted carboxyl modified PS spheres under the same conditions except that they used a 1:1 mixture of  $\text{H}_2\text{O} + \text{D}_2\text{O}$  to minimize sedimentation effects which can occur for larger colloids. In the investigated radial range between 11 nm and 253 nm they found a linear radial dependence of  $S_T$ . This experimentally observed behavior is in accordance with the theoretical prediction for solid particles. In contrast for soft particles a quadratic radial dependence of  $S_T$  is expected [68].

For the investigation of the radial dependence of  $S_T$ , the particle size has to be tuned. In the case that the particle density is kept constant, an increase in the particle volume fraction is implied so that particle-particle and particle-solvent interactions have to be considered [29, 69–74]. By keeping the volume fraction constant, the particle density will decrease if the particle size increases. It was shown for colloidal dispersions that in diluted systems particle-particle interactions can be neglected, while in the high concentration regime above approximately 10 vol%, particle-particle interactions dominate the concentration dependence of  $D_T$  [42]. An additional requirement for the model system is that the surface properties such as grafting density or charge density of the particles of different sizes should be the same. This prerequisite is difficult to fulfill for colloids, because for each particle size a separate synthesis has to be carried out, which leads in general to different surface properties.

Microemulsions are adaptable model systems, and their microstructure can be varied in size and shape without changing the chemistry of the constituents. They are thermodynamic stable systems of at least three components which are water (polar), oil (nonpolar) and surfactant (amphiphilic). In contrast to colloidal systems, they self-assemble spontaneously and can be regarded as thermodynamically stable but dynamic aggregates. In the isotropic phase, networks of bicontinuous phases are formed in the surfactant-rich region of the phase diagram. Additionally, in the water-rich or oil-rich region, oil-in-water (o/w) or water-in-oil (w/o) droplets are formed, respectively, which can be tuned in size and shape by varying the concentration and temperature. The surface characteristics of a microemulsion droplet do not change. In this work, nonionic microemulsions will be used as a model system for spherical droplets. The droplets surface structure, droplet-droplet interaction effects and their shape can be characterized by small angle neutron scattering

experiments. To our best knowledge the thermal diffusion behavior of microemulsions is rarely investigated [35].

## 1.1. Motivation and Objectives

This work results from a collaboration between the groups of Prof. R. Strey and PD Dr. T. Sottmann at the Universität zu Köln and Prof. J.K.G. Dhont and PD Dr. S. Wiegand (Forschungszentrum Jülich). The strength of this collaboration is the combination of the experimental expertise in microemulsions and amphiphilic systems in Köln with the thermal diffusion knowledge in Jülich. Amphiphilic systems have been selected, characterized and used as model systems to determine the thermal diffusion behavior of nanostructured fluids. The project was supported by the German Research Society (*DFG*).

First of all, nonionic sugar surfactants in water are studied below and above the critical micelle concentration (*cmc*). To our best knowledge, this is the first time, that the Soret coefficient will be systematically investigated in the vicinity of the *cmc*. Micelles are formed above the *cmc*. They coexist with single surfactant molecules. By means of surface tension measurements the *cmc* of three sugar surfactants with a fairly high *cmc* is determined at different temperatures. The surfactants differ in the number of hydrophilic and hydrophobic units. As the diffusion constant of the micelles is lower than of single molecules, it is expected that the Soret coefficient shows a distinct change at the *cmc* [34]. Furthermore it is expected, that at even higher surfactant concentrations the Soret coefficient shows a sign change from positive to negative with increasing concentration. The sign change behavior will also be investigated in a temperature dependence. Thermal diffusion experiments will be performed using the infrared thermal diffusion forced Rayleigh scattering (*IR-TDFRS*) setup. This method is optimized for aqueous mixtures [75]. For the determination of the dye influence, also measurements in the classical TDFRS setup [22, 75] are performed.

In the second part we will investigate the thermal diffusion behavior of microemulsions. These ternary mixtures of a polar, a nonpolar and an amphiphilic component [76] form w/o-droplets in an oil-rich  $1\phi$  region, o/w-droplets in a water-rich  $1\phi$  region, and networks of bicontinuous phases in the surfactant-rich region of the phase diagram. Within the  $1\phi$  regimes on the water- or oil-rich side of the phase diagram, these microemulsion droplets can be varied in size and shape by temperature or composition. The respective phase diagrams of H<sub>2</sub>O/*n*-alkane/pentaethylene glycol monododecyl ether (C<sub>12</sub>E<sub>5</sub>) mi-

croemulsions are determined. The measurements will focus on the emulsification failure boundary (*efb*) which confines the  $1\phi$  region to the lower  $2\phi$  region on the water-rich side. Along this boundary one finds spherical microemulsion droplets, and for a constant surfactant-to-water ratio, their size is tuned by a variation of the weight fraction of the oil component. Small angle neutron scattering (SANS) experiments provide information about the droplet shape, size and interaction effects. SANS measurements are performed to ensure the spherical shape of these investigated droplets. The first microemulsion under investigation, which serves as a model system to determine the radial dependence of the Soret coefficient, is the water/*n*-octane/ $C_{12}E_5$  system. Measurements in the IR-TDFRS are performed along the *efb* to ensure a spherical shape of the microemulsion droplets. Simultaneously with an increasing radius also the temperature had to be raised to ensure measurements close to the *efb* within the  $1\phi$  region. In order to separate the temperature influence on the Soret coefficient from the radial dependence we will perform systematic measurements by changing the *n*-alkane from *n*-octane to *n*-tetradecane. With this approach the same temperature can be achieved for different droplet sizes, but we have to accept a slight increase in the volume fraction of the droplets with decreasing chain length of the *n*-alkane. On the contrary we know from other studies [42] that the concentration dependence of the Soret coefficient is below 1 % and can be neglected if the concentration of the investigated aggregates in solution is below 10 vol%.

This work is structured as follows. The reader will be introduced into the field of thermodiffusion by discussing applications, theories and experiments. The used experimental setups are described. For completeness, also those setups are briefly mentioned which are used by the group in Köln, but the main focus will be set on the IR-TDFRS setup and an improved Michelson interferometer. We will introduce in the field of nonionic surfactants, especially the nonionic sugar surfactants. Additionally, a brief summary will be given into microemulsion systems and their phase behavior.

In the experimental part, the thermal diffusion properties of the binary system *n*-Octyl  $\beta$ -D-glucopyranoside ( $C_8G_1$ )/water is investigated in the vicinity of the *cmc* which is determined by surface tension measurements in Köln. The influence of an ionic dye is studied. Higher concentrations are investigated due to the sign change behavior of the Soret coefficient. These findings are confirmed by *n*-Heptyl  $\beta$ -D-glucopyranoside ( $C_7G_1$ )/water and *n*-Octyl  $\beta$ -D-maltopyranoside ( $C_8G_2$ )/water.

The thermal diffusion behavior of further  $H_2O/n$ -alkane/ $C_{12}E_5$  microemulsions is investigated. The phase boundaries of interest are determined in Köln, while the thermal

diffusion properties of the microemulsion droplets are studied in Jülich. SANS measurements are performed.

At the end of this thesis, the essential results of the experimental chapters will be concluded in a summary and an outlook will be given.

## FUNDAMENTALS

In thermal equilibrium the components of a mixture are homogeneously distributed. If a temperature gradient is applied the components start to diffuse and separate due to the applied thermal gradient and one component enriches at the warm side and the other at the cold side. This effect is called thermodiffusion or Ludwig-Soret-Effect named after the discoverers Carl Ludwig (1816-1895) [1] and Charles Soret (1854-1904) [2-4]. Ludwig published his observations in 1856 under the title "Diffusion zwischen ungleich erwärmten Orten gleich zusammengesetzter Lösungen" [*diffusion between unequally thermostated places of equally composed mixtures*]. Since that time, the experimental methods and theoretical concepts have been developed, but there is still no microscopic description for liquids. In contrast the thermal diffusion process is fully understood.

In the following three sections the basic principles of thermal diffusion, micellar solutions and microemulsions will be introduced.

### **2.1. General Remarks on Thermodiffusion**

This section summarizes recent theoretical and experimental developments and will give examples, where thermodiffusion plays a role in nature or industrial applications. In Sec.2.1.2 the framework of irreversible thermodynamics is introduced in which heat and mass flux are coupled by the so-called Onsager coefficients. The expression for the Soret

coefficient and the diffusion coefficients are derived. Sec.2.1.3 gives an overview of recent theoretical approaches to describe this separation process in a temperature gradient. Some theoretical models conform with experimental findings, although a general theoretical description for thermodiffusion is still an open question. Although a microscopic model is missing, some rules of thumb are known to predict the direction of the thermal diffusion. These rules relate to the physical and chemical properties of the system (Sec.2.1.4). An effect which cannot be explained by these rules is the sign change of the Soret coefficient with temperature or concentration which was observed for several systems (Sec.2.1.5).

Several experimental setups have been developed to measure the concentration separation in an applied thermal gradient. There are very different methods of applying the temperature gradient and detecting the separation effect. It will be focused on setups which are applicable to liquid systems. Selected setups are compared in Sec.2.1.6 and main advantages or disadvantages will be explained.

The goal of this work is the investigation of the influence of micelle formation around the critical micelle concentration on the thermal diffusion behavior and secondly the radial dependence of the Soret coefficient. Therefore, micellar systems and microemulsions are used as model systems and will be introduced in the end of this chapter.

### 2.1.1. Practical Applications and Processes in Nature

First important applications is the isotope separation which was developed and described [6, 12, 77, 78] in the early 1940ies. During that time, the enrichment of uranium became an important factor in the Manhattan Engineer District (*Manhattan-project*) [7, 8] in 1942 during 2<sup>nd</sup> world war. The enrichment was necessary as the natural concentration of usable uranium-235 for nuclear fission is approximately 0.7 %. Liquid UF<sub>6</sub> is separated in thermogravitational columns by cooling the inner column and heating the outer walls. As in more detailed explained in Sec.2.1.6, the thermogravitational column uses a combination of thermal diffusion and convection to separate components. The heavier U<sup>238</sup> tends to enrich at the cold side and U<sup>235</sup> at the warmer side. Convection transports the U<sup>238</sup> to the bottom while U<sup>235</sup> is transported on the top side of the column. Several columns are connected in a line to enhance the separation. In Oak Ridge, Tennessee, 2100 of these columns increased the concentration of U<sup>235</sup> to 1 %. Thus, this method was simple but energy expansive. Later, this technique was replaced by gas centrifuges [79].

The enriched material of 132 lbs ( $\approx 60$  kg) from this plant in Oak Ridge was used for the first nuclear bomb in 1945 [80].

In plants such as water lilies and alders, thermodiffusion ensures the availability of oxygen in the roots and rhizomes. Contrarily to the overground organs of the plant, where stored oxygen is produced and liberated by photosynthetically active plastids into the intercellular system, the roots require an external supply of oxygen to keep the oxygen concentration constant between 1-3 % for normal requirements of mitochondrial respiration. A temperature gradient between the leaves and roots induces the transport of oxygen through the intercellular system of the plant. The release of oxygen from the roots to the surrounding soil along a temperature gradient through the cell membranes is caused by *thermoosmosis*, which is actually thermodiffusion through a membrane [11]. This effect causes a mass flow from the low to the high temperature side and increases linearly with the temperature difference and with the mean temperature [81,82]. Thermoosmosis also works in single-component systems [83].

In oceans, thermal gradients occur due to the heating of the sun. This causes a vertical concentration grating, for instance of dissolved ions. In sea water of high salt content sulfate-depleted brines of extremely high salinity up to 25.7 % and high temperatures up to 56.5 °C at the bottom exist while above the salt concentration is halved [84] and the temperature is reduced to 44.3 °C. This contrast in salt concentration should be balanced by the Fickian diffusion but the thermal gradient causes an additional mass transport and the ions migrate to the brines [9]. This effect is used in *Solar Ponds* to store solar thermal energy. A Solar pond is a pool with salt water of three layers: a low-salinity top layer, a layer with a salt gradient from low salt concentration (low density) at the top to high salt concentration (high density) at the bottom, and a bottom layer of high-salinity. The pond's bottom material absorbs most of the solar thermal energy and heats the high salinity layer. This induces a temperature gradient from the warm (bottom) layer to the cold (top) layer so that the water density decreases with depth. This would imply a heat exchange. However, the salt gradient induces a density gradient which prevents heat transport from the bottom to the top layer. Temperatures of 90 °C can be reached in the bottom layer of a solar pond while at the top layer one measures temperatures of approximately 30 °C. The stored heat can be used for energy production or for heating [85–88].

The thermal flow field fractionation (*ThFFF*) is an established separation method for synthetic polymers and colloids [89] of different sizes of almost three to four orders of

magnitude [90–92] in organic and aqueous solvents. ThFFF offers shorter separation times and a better resolution of mass distribution for high molar weight solutions [93, 94], which are difficult to characterize by methods working with a stationary phase, such as size exclusion chromatography [95, 96]. A recent review by Cölfen and Antonietti [97] compares the ThFFF and other FFF methods with size exclusion chromatography.

### 2.1.2. Theory

There is no complete microscopic theory to explain the thermal diffusion effect. Only a few contributions such as collective effects in colloids or single particle effects of charged colloids have been analyzed on a microscopic level [29, 68, 71, 72, 98–103]. In the following, an approach in the framework of irreversible thermodynamics will be drafted.

Two reservoirs are considered of two different temperatures  $T_1$  and  $T_2$  which are energetically insulated from the environment. Both baths are coupled and allow the exchange of particles and heat energy. This exchange parameters are referred to as mass flux,  $J_1$ , and heat flux  $J_Q$ . The fluxes are taken relative to a center-of-mass system. In the following, the variables characterizing both baths, are denoted by 1 and 2, respectively.

**Energy production due to a heat flux.** First, the heat flux is considered. The driving force of the heat flux is a temperature gradient  $\Delta T$ . In the case of small changes, the relaxation of the system from nonequilibrium to an equilibrium state is a linear function and the entropy is increased by spontaneous processes [104]. The difference in entropy due to a temperature gradient is

$$dS = \delta S_2 - \delta S_1 = \frac{\delta Q_2}{T_2} - \frac{\delta Q_1}{T_1} \quad (2.1)$$

with the heat  $Q_1 = Q_2 = Q$ , the temperatures and entropies of both baths,  $T_{1,2}$  and  $S_{1,2}$ . Thus, the change in entropy is given by

$$dS = \delta Q \left( \frac{1}{T_2} - \frac{1}{T_1} \right) \quad (2.2)$$

and the time derivative of Eq.2.2 is given as the product of heat flow,  $J_Q$ , and the gradient of the inverse temperature,  $\nabla 1/T$ ,

$$\frac{dS}{dt} = \frac{dQ}{dT} \left( \frac{1}{T_2} - \frac{1}{T_1} \right) = J_Q \nabla \left( \frac{1}{T} \right) \quad (2.3)$$

with  $J_Q = Q/dt$ .  $dS/dt$  is the entropy production of the heat conduction process.

**Energy production due to a mass flux.** Also the mass transport can lead to an increase of the entropy. If a local thermal equilibrium is assumed, the Gibbs relation gives the total differential of the entropy [105]:

$$TdS = dU + pdV - \sum_i \mu_i dN_i \quad (2.4)$$

with the internal energy change,  $dU = 0$ , the work on the system,  $pdV = 0$ , and the chemical potential and number of particles of the  $i^{\text{th}}$  component,  $\mu_i$  and  $N_i$ . It remains for the two baths system

$$dS = -\frac{dN_1}{T} (\mu_2 - \mu_1) \quad (2.5)$$

wherein the deficit of particles in system 1 is equal to the gain in system 2:  $dN_2 = -dN_1$ . The difference in chemical potential is defined as  $\nabla\mu = \mu_2 - \mu_1$ . The time derivative follows as

$$\frac{dS}{dt} = -J_1 \frac{1}{T} \nabla\mu \quad (2.6)$$

with the mass transport from system 1 to 2,  $J_1 = dN_1/dt$ , and the thermodynamic force of the mass flux,  $X_1 = \nabla\mu$ . The entropy production depends on the difference in the chemical potentials. It is assumed, that no chemical reaction nor viscous flow or external forces occur [105]. According to Perronace [106] it follows:

$$\frac{dS}{dt} = J_Q \nabla \left( \frac{1}{T} \right) - J_1 \frac{1}{T} \nabla\mu. \quad (2.7)$$

In the following, the equality [102, 105] for the thermodynamic force of the heat flux,  $X_Q$ , is used:

$$-\nabla \frac{1}{T} = \frac{1}{T^2} \nabla T = X_Q. \quad (2.8)$$

In the linear approximation of irreversible thermodynamics, the flux  $J_1$  is factorized by a composition of thermodynamic forces,  $X_j$ , contributing to the entropy production and phenomenological coefficients,  $L_{1j}$ ,

$$J_1 = \sum_{j=1, Q} L_{1j} X_j. \quad (2.9)$$

with the expressions for the heat (Eq.2.3) and mass fluxes (Eq.2.6) denoted as  $Q$  and 1. Following, the heat flux is  $L_{QQ}$  and the Fick's diffusion is  $L_{11}$ . Two additional irreversible

fluxes  $L_{Q1}$  and  $L_{1Q}$  are described as linear functions of the thermodynamic forces  $X_j$ . Thus, a temperature gradient can induce a mass transport ( $L_{Q1}$ ) which is described as the Soret effect [106], and the reverse Dufour [107] effect describes a heat flow due to a concentration gradient ( $L_{1Q}$ ). According to Onsager relations,  $L_{ij}$  is a symmetric matrix which couples both transport processes, the heat and mass.  $L_{ij}$  satisfies the conditions  $L_{QQ}, L_{11} > 0$  and  $L_{QQ}L_{11} - L_{Q1}^2 = 0$  using  $L_{1Q} = L_{Q1}$  [104]. It follows

$$J_Q = J_{QQ} - \frac{1}{T^2} \nabla T - L_{Q1} \frac{1}{T} \nabla \mu, \quad (2.10)$$

$$J_1 = J_{1Q} - \frac{1}{T^2} \nabla T - L_{11} \frac{1}{T} \nabla \mu. \quad (2.11)$$

Eqs.2.10 and 2.11 are valid for an isotropic system in which, in equilibrium state, all appearing thermodynamic forces have the same magnitude in all directions. The chemical gradient is replaced using the Gibbs-Duhem-relation [108, 109] under isothermal and isobaric conditions:

$$\nabla \mu = \frac{\mu_{11} \nabla w_1}{w_2} \quad (2.12)$$

with the concentrations  $w_{1,2}$  of the concentrations of component 1 and 2, respectively. Following,

$$J_Q = J_{QQ} - \frac{1}{T^2} \nabla T - L_{Q1} \frac{1}{T} \frac{\mu_{11} \nabla w_1}{w_2}, \quad (2.13)$$

$$J_1 = J_{1Q} - \frac{1}{T^2} \nabla T - L_{11} \frac{1}{T} \frac{\mu_{11} \nabla w_1}{w_2}. \quad (2.14)$$

From experimental point of view, the Soret coefficient is a measure of concentration separation due to a temperature gradient in a steady state where the mass flow  $J_1$  is zero. Thus, it depends on the concentrations  $w_1$  and  $w_2$ ,

$$S_T \Big|_{J=0} = - \frac{1}{w_1 w_2} \frac{|\nabla w|}{|\nabla T|} \quad (2.15)$$

If Eq.2.14 is now transposed to an expression of the gradient ratio

$$\frac{|\nabla w|}{|\nabla T|} = \frac{L_{1Q}}{L_{11}} \frac{w_2}{T^2 \mu_{11}}, \quad (2.16)$$

it is inserted in Eq.2.15 and thus yield an expression of  $S_T$  as function of the phenomono-

logical coefficients:

$$S_T = \frac{L_1 Q}{L_{11}} \frac{1}{T^2 \mu_{11}} \frac{1}{w_1} \quad (2.17)$$

for  $J_1 = 0$ .

Fick's law relates the mass flux  $J_1$  with a concentration gradient  $\nabla w_1$

$$J_1 = -\rho D \nabla w_1 \quad (2.18)$$

with the density,  $\rho$ , and the diffusion coefficient,  $D$ . In the absence of a temperature gradient, the first part in Eq.2.14 vanishes and the mass flow expressions given by Eq.2.18 and Eq.2.14, lead to:

$$\rho D \nabla w_1 = L_{11} \frac{1}{T} \frac{\mu_{11} \nabla w_1}{w_2}. \quad (2.19)$$

Hence, the diffusion coefficient is a function of the phenomenological coefficient

$$D = L_{11} \frac{1}{T} \frac{\mu_{11}}{w_2 \rho}. \quad (2.20)$$

Finally, the thermal diffusion coefficient is the product of Soret and diffusion coefficient, and using Eqs.2.17 and 2.20, it is obtained

$$D_T = L_1 Q \frac{1}{T^2} \frac{1}{w_1 w_2 \rho}. \quad (2.21)$$

If  $w_2 = 1 - w_1$  is used, Eq.2.15 can be modified to

$$S_T \Big|_{J=0} = -\frac{1}{w_1(1-w_1)} \frac{|\nabla w|}{|\nabla T|} = \frac{D_T}{D} \quad (2.22)$$

Eq.2.22 can be applied in the case that  $w \approx w_0$  with the initial concentration in equilibrium,  $w_0$ , and the concentration in the steady state in the presence of a temperature gradient,  $w$ , as the separation ratio is small compared to the initial concentration.

### 2.1.3. Theoretical Approaches

Several methods have been used to describe the effect of thermodiffusion, like the Chapman-Enskog theory which describes the thermal diffusion effect in gaseous mixtures [26, 27, 110, 111]. This theory is limited and fails for denser systems like fluids. To a certain extend, the framework of irreversible thermodynamics [112, 113] is used and the

transport coefficients are derived by the Onsager coefficients. Regarding the single-particle and particle-particle interactions in fluids, kinetic theories [100, 114, 115] can be used to express these interactions in terms of potentials. These potentials consider temperature, concentration or charge effects. Molecular dynamic simulations [51, 102, 116–119] allow to study the thermal diffusion properties of a microscopic system. Especially low-molecular weight mixtures have been studied to investigate systematically mass and moment of inertia effects [120]. Force fields are assumed, which define the particle interactions. The method of Monte Carlo simulations [121] is a widely used approach for the investigation of lattice gas dynamics. A potential is introduced to describe the nearest neighbor interactions of a  $N$ -particle system. A stochastic formalism is used to calculate the probability of a particle to move in the lattice.

Some of the theoretical approaches yield comparable results to experimental findings under certain restrictions on the investigated model system but a general description of the Soret effect on a molecular level is still lacking. In the following, theoretical approaches will be introduced which describe the radial dependence of the Soret coefficient or predict a sign change of the thermophoretic motion in fluids. As most of the theoretical approaches assume charged particles, this section also sheds some light on charged systems.

**Radial dependence of the Soret coefficient.** Würger [30, 68] calculated a linear radial dependence of  $S_T$  for spherical macromolecules with neglecting particle-particle interactions. This linearity stems from the boundary layer approximation that the particle-solvent forces are short-ranged. Then,  $D_T$  becomes independent from the particle radius [122–124]. This approximation is not valid for semidilute systems where  $D_T$  depends on the molecular weight [125] or volume fraction [126]. Morozov considered a theoretical approach for single-particle interactions in ionic ferrocolloids. By the assumption of a force balance of electrical and viscous forces he found a linear radial dependence of  $S_T$  [101, 103].

A quadratic radial dependence of the Soret coefficient is derived for soft particle interfaces. In this case the sticky boundary condition of short-ranged interaction forces fails [99]. Charged colloids with a thin double layer have been investigated by Ruckenstein [57]. He suggested, that the free energy reduction is responsible for the thermophoretic motion. The thermophoretic motion of colloidal particles is assumed to be driven by an interfacial tension gradient. This gradient is induced by a temperature gradient since the Debye-Hückel screening length depends on the temperature. This approach was recently used

by Piazza and Guarino [37] to express the Soret coefficient as a quadratic function of the Debye-Hückel screening length.

The approach introduced by Ruckenstein turned out to be wrong [127]. Dhont [127] suggested, that it is only the reversible work that determines  $S_T$  and not the reduction of free energy. Consequently, Dhont and Briels [29] expressed the Soret coefficient as a linear function of the Debye-Hückel screening length.

Fayolle *et al.* [128, 129] gave an equation for the thermal diffusion coefficient using the Stokes equation with a force term arising from the electric stress in the diffuse double layer of charged colloids. They predict for highly diluted colloids of small valencies, that  $S_T$  scales with the squared of the particle radius and depends linearly on the Debye-Hückel screening length.

**Sign change behavior.** A sign change of the thermophoretic motion originates from changes in the particle-solvent interfaces or from interparticle interaction effects. Thus, theoretical approaches have introduced several contributions to the Soret coefficient which describe these effects. Bringuier and Bourdon [100] expressed the Soret coefficient as a function of the derivative of the total internal energy with temperature. In the case that the internal energy becomes temperature dependent, the contributions to the internal energy determine if the Soret coefficient is increased, decreased or changes the sign. Contributions to the internal energy can be single-particle and particle-particle interaction effects or terms describing charge effects.

Dhont [71, 72] assumed a temperature dependent interaction potential between colloidal spheres to derive the transport coefficients. If the interaction between the colloidal surface and the solvent is known, the thermal diffusion coefficient can be calculated. The temperature dependence of the potential turns out to induce a sign change of the thermal diffusion coefficient with changing temperature or concentration in a certain parameter range.

Reverse non-equilibrium molecular dynamics simulations have been performed by Zhang and Müller-Plathe [116] to derive the thermal diffusion properties of dilute polymer solutions. They have shown that at constant temperature and concentration, a better solvent quality causes a higher affinity for the polymer to the cold region. The Soret coefficient changes sign from negative to positive when the solvent quality becomes bad. A recent theoretical approach by Luettmmer-Strathmann *et al.* [31, 32] has indicated a similar trend for polymers in water-ethanol solutions. By changing the solvent composition a sign

change of the Soret coefficient was induced.  $S_T$  turned from negative to positive as the water concentration of the solvent was increased.

#### 2.1.4. To the Warm or to the Cold?

There are a few rules of thumb which help to predict which component enriches in the cold or in the warm.

Considering the size or weight distribution, the larger or heavier molecules tend to go to the cold region [130]. Almost all polymers accumulate in the cold. This is not a general feature but depends on specific interactions and the solvent quality. Exceptions are polyvinyl alcohol in water [17] and poly(ethylene oxide) in mixtures of ethanol/water with a high ethanol content [130,131]. As long as the mixtures consist of almost spherical nonpolar molecules the heavier component enriches in the cold region [132]. But even for the nonpolar *n*-heptane/benzene mixture this simple rule of thumb fails [133]. Only if the highly branched and more symmetric heptane isomer 2,3,3-trimethylbutane is used instead of *n*-heptane the heavier component goes to the cold. These results indicate that the more symmetric molecules have a stronger tendency to accumulate in the cold.

Investigating the three structural isomers of the aromatic hydrocarbon dimethylbenzene, it was shown that the para-form moves to the warm region, the meta-form stays between both regions, and the ortho-form moves to the cold region [134].

For polymers and colloids also changes at the interface between the solute particle and the solvent need to be considered. In some cases structural variations of the solvent due to concentration changes of a solvent mixture [47,130,131] or temperature effects [61] lead to a sign change in  $S_T$ . For charged colloids also the double-layer contributes to the thermal diffusion properties [29] so that due to the complex chemical and electrostatic interactions simple rules of thumb can not be derived.

#### 2.1.5. Sign Inversion of the Soret Coefficient

A sign change of the Soret coefficient is a special case of thermodiffusion which cannot be explained by the rules of thumb in Sec.2.1.4. If a sign change is observed, mainly by a variation in temperature or concentration, the component enriches at the opposite region. This effect has been observed in many gaseous mixtures [135–139] and fluid systems [58,62,117,125,131,140]. In the following, only liquids will be discussed.

The assumption by Grew [137] defined three contributions to the thermal diffusion factor ( $\alpha_T = S_T \cdot T$ ): the difference in mass and in the diameter of the molecules and a contribution which refers to the interaction forces between the molecules. The first and the second contributions are suggested to be independent from a variation of concentration. The third contribution depends on concentration and relates to the collision diameter of the molecules which differs from the mean diameter due to interaction forces [138] and which causes the sign change with concentration. Later, a similar approach by Debuschwitz and Köhler [141] defined three contributions to the Soret coefficient which are the mass, the moment of inertia and a chemical contribution. This chemical contribution will be discussed in the following.

Wittko and Köhler [63] studied mixtures containing protonated and deuterated cyclohexane. At equal mole fractions the Soret coefficient turns from negative to positive values if the difference in molecular mass,  $\Delta M$ , between solvent and solute increases and a constant slope for  $\partial S_T / \partial \Delta M$  is derived [142]. The same slope was derived for the isotopically substituted cyclohexane [141]. As isotopic substitution is a powerful method to change the mass of a molecule by keeping the chemical properties of the solute and leaving the intermolecular potential almost unaffected.

The investigation of the thermal diffusion properties of the systems di- and tri-glycols in ethanol [143] indicated a sign change behavior of  $S_T$  with increasing chain length of the glycols. This is reasonable as ethanol becomes a bad solvent for the long-chained glycols.

Experimental studies [59, 62, 75, 144–148], calculations [31] and simulations [51, 149] of low-molecular water-ethanol mixtures have indicated a sign change of the Soret coefficient from positive to negative with increasing water content. Polyakov and Wiegand [59] investigated mixtures of associated solvents. A sign change was observed at a certain concentration at which the Soret coefficient is independent from temperature for solutes which show pronounced hydrophilic interaction effects with the solvent due to their polarizability [150]. Prigogine [151] claimed that the investigated mixtures are non-ideal solutions. Otherwise, no concentration dependence of  $S_T$  should be observed. Some papers indicate, that the sign change of  $S_T$  occurs when the hydrogen bond network breaks [62, 152, 153]. Rousseau *et al.* [51, 149] discussed the  $S_T$  sign change by means of changes in the particle-particle interactions. Therefore, the strength of solute-solute or solvent-solvent interactions, denoted as *intra-species* interactions, the strength of solute-solvent interactions (*inter-species* interactions) are considered. In the case that the inter-species interaction are larger than the intra-species interactions, a sign change of the thermophoretic mo-

tion is observed. This can be achieved experimentally by variation of the composition, concentration or temperature.

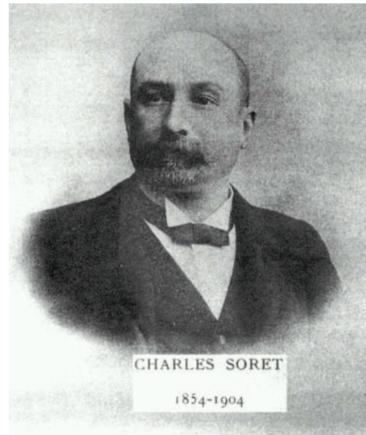

Recently, Vigolo [33] reported a sign change of  $S_T$  influenced by charges in micellar SDS solutions by adding sodium hydroxide (NaOH). The highly mobile  $\text{OH}^-$ -ions in a thermal gradient induce a stationary electric field which is responsible for electrophoretic transport phenomena of the SDS micelles. By increasing the ion concentration, the Soret coefficient turns from positive to negative.

A temperature induced sign change of  $S_T$  was observed for lysozyme solutions [48, 64, 154] where  $S_T$  goes from negative to positive values with increasing temperature. It was shown that this effect results from thermally induced gradients of the interfacial tension. The sign change temperature is shifted with increasing salt concentration.

Also in colloidal suspension a sign change has been investigated. Ning *et al.* [42] studied the thermal diffusion behavior of octadecyl coated silica particles with a radius of 27 nm in toluene for low and high concentrations. At high dilution, the Soret coefficient is independent from concentration and only differs for different temperatures. Low temperatures cause a negative Soret coefficient which turns to positive values for higher temperatures. Above a concentrations of 10 vol%, colloid-colloid interactions affect the thermal diffusion behavior and  $S_T$  decreases with increasing concentration and a sign change occurs. This decreasing behavior has also been observed for polystyrene in toluene [155–157] and was interpreted as an increase of the local viscosity approaching the glass transition [158].

For ferromagnetic colloids, Morozov [103] shows that the sign of  $S_T$  is a function of the ratio of double layer thickness and radius, and of the electric potential. It was found that the colloids tend to move to the cold for low electric potentials and an infinitely small double layer thickness. If the double layer thickness increases, and the electric potential reaches a certain strength, the colloids enrich at the warm region.

For a polymer solution of Poly(*N*-isopropylacrylamide) (PNiPAM) in alcohols a variation of the molecular structure of the solvent can cause a sign change of the Soret coefficient. Kita and Wiegand [140] observed that the Soret coefficient changes from positive to negative with increasing number of carbon atoms of the alcohol. On the other hand, the sign change temperature decreases with increasing carbon atom numbers. For the system PNiPAM-ethanol, a sign change occurs with increasing temperature from positive to negative  $S_T$ . The sign change temperature is close to the coil-globule transition temperature of PNiPAM in water at which PNiPAM goes from a swollen hydrated state into a shrunken dehydrated state. Thus, above the phase transition temperature, the former

*Figure 2.1.:* Charles Soret (23<sup>th</sup> Sept 1854 - 4<sup>th</sup> Apr 1904) [159].

hydrated water molecules lower the local solvent quality around the polymer and  $S_T$  becomes negative. A Soret sign change due to a change in the solvent quality has also been observed for PEO in a mixed solvent of water and ethanol [31,32,46,47,62] from a positive to a negative Soret coefficient for increasing water concentration. The sign change occurs at a solvent composition where large structural changes take place.

### 2.1.6. Experimental Setups to study Thermal Diffusion

Several experimental methods have been used to study the thermal diffusion behavior of liquid mixtures. The methods differ in the way how a thermal gradient is applied and the separation effect is detected. Some of the methods are convection-free, others not. In the last two decades different optical methods have been developed which work only analytically and cannot be used to separate different components. In the following, an overview of the methods is given.

Charles Soret (Fig.2.1) was the first scientist who performed systematic measurements of the mass separation in a thermal gradient. He used different kind of tubes which are cooled from the bottom and heated from the top. The hot side was 78 °C and the lower temperature was between 18 °C and 15 °C [2]. The tube length was 0.3 m, so that the temperature gradient was in the order of 200 K/m. The separation effect of ionic components was analyzed after a measuring time of up to 56 days [4]. He obtained a separation ratio of 1.1 % and the ionic component got enriched at the cold end.

A vertical thermogravitational column as sketched in reference [160] was introduced by Clusius and Dickel [77] in 1939 to measure mass separation in a vertical narrow gap with

a height-to-width ratio of larger than 100. The gap is heated or cooled from the side walls and the Soret effect causes a mass transport to the warmer or colder wall. Convection implies, that an additional mass transport parallel to the walls occurs, such that due to the density change at the warmer wall, the convection directs to the top and at the cold wall to the bottom. This induces a vertical concentration gradient if the denser component diffuses to the cold. This setup is a so-called 2-point measurement setup and the concentration ratio of the top or bottom is measured. Nowadays multi-point setups are used [145]. The thermogravitational column allows only the determination of the thermal diffusion coefficient. The diffusion or Soret coefficient cannot be obtained. Thus, it is more applicable for quantitative mass separation analysis, like isotope [12] or gas separation [161–165], and competes with HPLC techniques. Main disadvantages are the build-up of a sufficient strong thermal gradient of 1000 K/m [160], the long equilibration time of more than 90 hours in the case of organic low molar weight mixtures and the fairly large sample volume in the order of 3-27 ml [13, 166].

Recently, the thermogravitational column was used to investigate ternary systems [167–169]. Following the approach by Larre *et al.* [170], the behavior of a ternary system can be estimated by considering the corresponding binary systems of the three containing components. A comparison of the experimental results by Königer *et al.* [171] and Blanco *et al.* [169] revealed pronounced differences in the determined thermal diffusion coefficients of the ternary system.

One of the weaknesses of the thermogravitational columns is, that it only measures the thermal diffusion coefficient and not the mass diffusion coefficient which is required to calculate the Soret coefficient. The mass diffusion coefficient can be obtained by coupling the thermogravitational column with Laser Doppler velocimetry (*LDV*) which measures the vertical flow velocity amplitude [145]. Light of crossed laser beams is scattered at flowing particles. Due to the Doppler effect, the scattered frequencies are shifted to the reference beam frequencies which results in a beat frequency at the detector. The flow velocity is calculated with a high accuracy from the crossing angle, the wavelength of the lasers beams and the frequency shift. This allows the determination of  $D$ .

In the thermal lens setup [18] a laser with a Gaussian intensity profile is used to write a temperature profile in a sample. An absorption in the order of 1-2 cm<sup>-1</sup> of the sample at the laser wavelength is sufficient. The temperature profile induces a refractive index profile in the sample, such that the refractive index is low in the center of the beam, so that the sample acts like a diverging lens. The additional mass transport in a two com-

ponent mixture induces additionally a concentration lens (Soret lens), which amplifies or diminishes the refractive index profile [48] induced by the thermal effect. The transmitted intensity, in some cases of an additional read-out laser [172,173], is measured versus time. A steady state is attained within some seconds for low-molecular weight solutions but also high molar weight solutions of proteins or polypeptide solutions can be measured. The investigation of large colloids with a radius of 100 nm and more is not possible, because then convection influences the experiment. If the natural absorption of the solvent is insufficient, a photostable dye is added which has to be inert and should not alter the chemical or physical properties of the sample under investigation [174,175]. A very strong absorption should be avoided due to nonlinear effects and a low excitation power reduces convection effects. The thermal lens technique is applicable to probe mixtures with a high optical contrast [175].

Giglio and Vendramini [16,17] described a laser beam deflection technique which probes the build-up of a concentration gradient in a Soret-cell with a laser beam. A similar setup is still used by Piazza *et al.* [37,146] and the group of Köhler *et al.* [144,171]. The sample cell with an optical length of a few centimeters is confined between two horizontal metal plates with a gap width between 0.5 mm and 1 mm. Between these plates a temperature gradient is built up. This temperature gradient ( $\approx 14$  K/cm [157]) induces a concentration gradient due to the effect of thermodiffusion. Both gradients cause a refractive index gradient at which a horizontally aligned laser beam is deflected. The position of the laser beam is monitored with time by a position-sensitive detector with a resolution of a few  $\mu\text{m}$ . A steady state is reached within less than one hour for a dodecane/isobutylbenzene/1,2,3,4-tetrahydronaphthalene (nC<sub>12</sub>-IBB-THN) system [144]. Putnam and Cahill [176,177] recently developed a new micron scale beam deflection setup where an oscillating temperature gradient is induced. The beam deflection technique is applicable for molecular and polymer solutions as well. Also the measuring volume is reduced to approximately 1/10 ml. Recently, the normal beam deflection method was extended by a second read-out laser at a different wavelength to measure ternary systems [171] following the approach of Haugen *et al.* [178] that a system of  $n$  components requires deflections from  $(n - 1)$  beams of different wavelengths.

The thermal flow field fractionation (*ThFFF*) was employed in 1975 by Giddings [19,20] for polymer separation. Modifications of this technique are still used [93,179–182] to analyze or separate biomolecules or to characterize the molecular weight and composition of polymer components [183]. This technique is sensitive to surface effects [89,184] and thus allows colloidal surface analysis. In *ThFFF*, a temperature gradient of up to  $4 \cdot 10^5$  K/m

for polymer solutions ( $M_w \approx 10^5$  g/mol) is vertically applied to a thin channel of 0.1 mm in width [185] and a volume of approximately 1 ml [186]. In a parabolic-like velocity profile the test sample is transported through a channel. In a perpendicular thermal gradient one component accumulates at the cold wall of the channel into regions of a slower flow velocity. Thus, this component enriches in slower flow regimes and elute last from the channel while other components which do not enrich in the cold region elute first. The overall measuring time is in the range of minutes to hours [45]. The ThFFF technique can be used to determine the thermal diffusion coefficient of different polymer solutions and colloidal suspensions which show a large distribution of molecular weights [185] from  $10^3$  to  $10^7$  g/mol [90–92]. Only small amounts of sample material of some nano-gram to micro-gram are required. The thermal diffusion coefficient of a retained solute is obtained from the retention time ratio to an unretained solute and the temperature difference between the channel walls [97].

Braun and Libchaber [21] employed in 2002 a fluorescence method to investigate the separation of DNA strains ( $M_w \approx 1.6 \cdot 10^7$  g/mol) in an aqueous buffer solution. In this method an IR-laser at 1480 nm heats an aqueous sample so that a temperature gradient of approximately 1-2 K is induced in a thin chamber of 10-25  $\mu\text{m}$ . Thus, temperature gradients of  $1 \cdot 10^6$  K/m can be realized [49]. The chamber volume is 2  $\mu\text{l}$ . In this setup, two measurements need to be performed to measure the temperature and the concentration profile. In a first measurement the temperature gradient applied to the solvent is determined. Therefore, a temperature sensitive fluorescent dye is added to the solvent. Differences in the temperature profile are monitored by differences in the fluorescence intensity. The addition of a fluorescent dye can lead to deviations of the measured temperature profile as the fluorescent dye also obeys thermodiffusion principles and is not homogeneously distributed in the sample if a temperature profile is applied. In a second measurement, dye-labeled solutes accumulates in the temperature gradient at the cold or at the warm. The time dependent fluorescence intensity is monitored with a camera. A steady state is attained within 300 s (for DNA strains). Convection inside the chamber is opposed to the thermophoretic repulsion and increases with the chamber thickness. Above a certain convection strength particles get trapped. Both diffusion coefficients can be evaluated from the time dependence of the fluorescence intensity signals in the cold region. The probed solute size is in the nano- to micrometer range [65, 125].

In the thermal diffusion forced Rayleigh scattering (*TDFRS*) technique [22] a holographic interference grating [187] is written in the sample. Due to absorption which is achieved by the addition of an inert dye, the intensity grating is converted into a sinusoidal temperature

gradient. The fringe spacing of the temperature grating is approximately  $20\ \mu\text{m}$  and a temperature difference of  $20\text{-}100\ \mu\text{K}$  can be achieved [24, 25]. Due to thermodiffusion a sinusoidal concentration grating builds up. These sinusoidal changes of temperature and concentration are accompanied by a refractive index modulation which is read out by a HeNe-laser which is not absorbed by the sample and does not alter the temperature. This technique was recently modified for aqueous samples [39, 40], such that the wavelength of the writing laser is chosen at a weak absorption band of water at  $980\ \text{nm}$  [75]. Thus, in the IR-TDFRS setup the addition of dye is not required in aqueous mixtures. Depending on the used sample cells, sample volumes of less than  $0.5\ \text{ml}$  are possible. The thin cell geometry avoids convection effects and short measurement times are achieved for low-molecular systems due to a narrow fringe spacing. The measurable size ranges from low-molecular systems up to polymer solutions of  $10^7\ \text{g/mol}$  [188, 189]. The main disadvantage is the restriction to binary systems. Ternary mixtures could be studied, if another read-out laser with a different wavelength is used, and if the components show a sufficient dispersion in their refractive index increments.

## 2.2. Binary Micellar systems

Amphiphilic molecules can form micelles in solution in order to minimize the free energy of the system. Micellization occurs as function of concentration or temperature where above a certain concentration or below a certain temperature, micelles will form and coexist with surfactant monomers in the bulk phase. This specific concentration or temperature is called critical micelle concentration (*cmc*) or critical micelle temperature (*cmt*), respectively. Accordingly, micellar systems can be tuned slightly in size or shape by varying the concentration or temperature.

So far the thermal diffusion behavior of sugar surfactants has not been studied although the properties this class of surfactants are defined by amphiphilic properties of the surfactant, which will be discussed in Sec.2.2.1. Micelles in water are formed in that way, that the hydrophilic part of the surfactant molecule aligns in the micelle-solvent interface and the hydrophobic forms the core of the micelle. The micellization in aqueous sugar surfactant systems starts at a fairly high concentration compared to other surfactants. This allows a precise investigation of the thermal diffusion properties close to the *cmc*, which are ruled by monomers below the *cmc* and by micelles above the *cmc*, respectively. Results will be shown in chapters 4 and 5.

### 2.2.1. Nonionic Sugar Surfactants

Nonionic sugar surfactants show an amphiphilic behavior due to a hydrophilic sugar head group and a hydrophobic carbon chain. Compared to other surfactant classes, i.e. nonionic alkyl polyglycoether ( $C_iE_j$ ) surfactants [190], they are completely biodegradable and can be produced from renewable resources [191,192]. In the following, the general expression  $C_iG_j$  is frequently used, where  $C_i$  denotes the number of  $CH_x$ -units in the hydrophobic chain and the head group units are denoted as  $G_j$  with  $j$  being the number of sugar units in the hydrophilic head.

Over the years sugar surfactant systems have been investigated experimentally and theoretically [193–195]. These biocompatible surfactants have frequently been used to study the dissolution and formation of biological membranes and the stabilization of proteins [196–200]. In a clinical context, these surfactants cause marginal skin irritation [201]. Alkyl-monoglucoside surfactants have been used in the formulation of microemulsions for the emulsification of mineral oils [202] and it turned out, that these surfactants are effective amphiphiles [203].

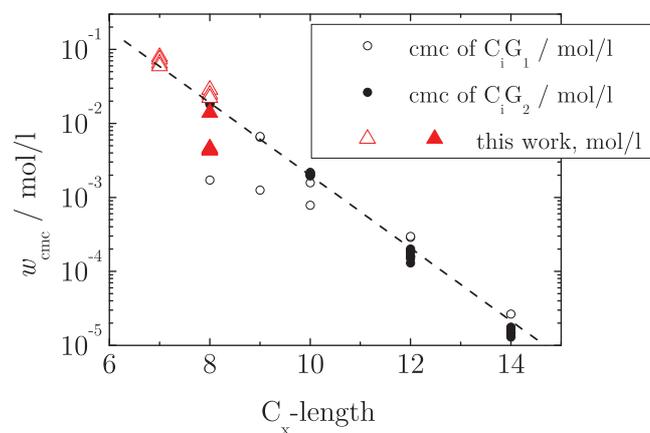

For a systematic study of the amphiphilic properties of the sugar surfactants, the number of head group units  $j$  and alkyl groups  $i$  can be varied. We will concentrate on three sugar surfactants:  $n$ -Octyl  $\beta$ -D-glucopyranoside ( $C_8G_1$ ),  $n$ -Heptyl  $\beta$ -D-glucopyranoside ( $C_7G_1$ ) and  $n$ -Octyl  $\beta$ -D-maltopyranoside ( $C_8G_2$ ). All surfactants are studied in water.

Many groups investigated the micellar structure of sugar surfactants using different methods. Most studies were performed on water/ $n$ -Octyl  $\beta$ -D-glucopyranoside systems. The concentration dependence of the micellar size and shape of  $C_8G_1$  was studied theoretically [54] and experimentally [204–213]. A compact and spherical shape of micelles with a radius of 2.29 nm to 2.35 nm was found which is almost independent from surfactant concentration above to the  $cmc$ . The measured radii are confirmed by a theoretical approach which compares the maximum micelle radius with the maximum length of the surfactant molecule [207]. The theoretical approach calculates the radius to 2.16 nm [214] including a hydration layer of water molecules. At higher concentrations ( $w \approx 2 \cdot cmc$ ), the shape turns to rod-like and more heterodisperse micelles due to a maximum accessible micellar diameter which is defined by the length of the surfactant monomers. The micelles grow in length, because both hemispherical ends of the rod are energetically unfavored constellations [205]. Thus, larger rod-like micelles are preferred instead of an increase of spherical micellar number density. At low concentrations slightly above the  $cmc$ , attractive interaction forces govern the micellar behavior while at higher concentrations,

repulsive steric interactions between the micelles are dominant (for  $w \approx 30 \cdot cmc$ ) [206]. Contrarily, D'Aprano *et al.* [208] found that the  $C_8G_1$ -micelles are already at the *cmc* of rod-like shape and do not change their structure at higher concentrations. These findings for  $C_8G_1$  have also been confirmed for other glucoside micelles ( $C_iG_1$ ,  $i = 7 \dots 10$ ) by Zhang *et al.* [205].

For the  $C_8G_2$ -micelles a spherical shape has been determined [215, 216] which is independent of temperature or concentration. Hydrophilic forces between the head groups play an important role in the micellar shape [215] while the hydrophobic alkyl chain favors the formation of micelles to reduce the free energy [217]. This effect becomes stronger for longer carbon chain length (by 0.825 kcal/mol per  $CH_2$ -group [214] assuming a constant number of head group units). Due to the strong influence of the hydrophilic forces on the micellar structure, polyglucosides like  $C_8G_2$  prefer spherical micelles to increase the volume per head group in the micellar layer, while monoglucosides like  $C_8G_1$  tend to form rod-like structures to reduce unfavorable hemispherical end caps where water is in contact with the carbon chains.

Another aspect in this work will be the determination of the temperature dependence of the *cmc*. Generally, the *cmc* decreases with increasing temperature [212, 218, 219] for nonionic surfactants, while for ionic surfactants the *cmc* increases with increasing temperature. On the other side, experiments on nonionic polyoxyethylenated and sugar surfactant systems [220–222] indicated a decrease of the *cmc* for increasing temperature which turns into an increase at higher temperatures. A minimum *cmc* has been determined between 40 °C and 50 °C. First theoretical predictions were made by Israelachvili [213], stating that the temperature dependence of *cmc* is more pronounced with increasing carbon chain length. Accordingly, for the short chained  $C_8G_1$ , the spherical micelles does not show any remarkable temperature dependence of their size [223]. The solubility of the nonionic surfactant molecule decreases with increasing temperature and the surfactant becomes less hydrophilic due to an increase of hydrophobic forces [215, 224]. Hence, the growth of micelles which is favored by the hydrophobic carbon chains becomes minor, and the micellar size reaches a maximum size at a certain temperature. Aoudia *et al.* and Kameyama *et al.* determined the aggregation number of  $C_8G_1$  in water for several temperatures and found a maximum aggregation number at  $T = 35$  °C [220] or  $T = 36$  °C [212], respectively. The temperature agrees nearly with the temperature of the minimum *cmc* value. Sugar surfactants exhibit a comparable high aggregation number due to the strong hydrophilicity of the head group units [194, 202, 212]. Literature results vary between 70 and 87 for  $C_8G_1$ . The first number was determined in sedimentation equilibrium studies at 20 °C by

**Figure 2.2.:** The measured critical micelle concentrations in this work (red symbols) and from literature (black symbols) versus the carbon chain length are compared. Literature data are taken from references given in Tab.2.1. The dashed line is a linear fit with respect to the logarithmic scaling of the concentration axis. Aqueous mixtures of maltosides (solid symbols) and of glucosides (open symbols) are shown. The lower filled red triangle represents the cmc of a C<sub>8</sub>G<sub>2</sub> batch, which was contaminated. This batch was not used for further measurements.

Roxby and Mills [211], and the latter one was measured at 22 °C by Kameyama *et al.* [212] using light scattering methods.

A general overview on recent *cmc* measurements for glucosides and for maltosides at room temperature is given in Fig.2.2. The plotted data refer to Tab.2.1 for glucosides, and to Tab.2.2 for the maltosides, respectively. In a log-linear plot of the *cmc* versus the alkyl chain length of the surfactant a linear dependence is found (dashed line in Fig.2.2).

### 2.2.2. Consequences for ongoing Measurements

For the three surfactants under investigation it is expected, that (i) the increase in the alkyl chain causes approximately a three higher *cmc* of C<sub>7</sub>G<sub>1</sub> compared to C<sub>8</sub>G<sub>1</sub> and C<sub>8</sub>G<sub>2</sub> in water which show approximately the same *cmc*. The determined *cmc* in a temperature range between 15 °C and 40 °C should decrease with increasing temperature for all investigated surfactant systems. (ii) In the low concentration regime close to the *cmc*, we expect the maltoside micelles to be spherical in shape due to strong repulsive forces of the head group units. (iii) Glucoside micelles are also assumed to be spherical if the concentration is slightly above the *cmc*, while at higher concentrations, ellipsoidal glucoside micelles are expected. (iv) In the investigated concentration range the surfactant

micelles grow with increasing surfactant concentration while at constant concentration, a variation in temperature should leave the micellar size unaffected.

## 2.3. Microemulsion Systems

Schulman *et al.* [245] firstly introduced the definition of a microemulsion to describe dispersions consisting of uniform spherical droplets of oil or water in a continuous phase which are stabilized by an amphiphilic component. Microemulsions are thermodynamic stable and nanoscopic structured systems of at least three components. These components are polar (A), non-polar (B) and amphiphilic (C).

The interplay of the three components results in a complicated phase behavior [76, 246–249], wherein several states occur (see Sec.2.3.1). In some phases, microemulsion droplets are formed. Two types of droplets are known: o/w and w/o droplets. These droplets are similar to micellar aggregates but the additional component is enclosed in the droplet. For o/w droplets, oil is embedded, while for w/o ones, it is water. Microemulsions are thermodynamically stable systems. In a dynamic equilibrium, the exchange of molecules with the environment is possible which is in the order of microseconds but the stability of droplets is found in timescales of several seconds for typical low molecular weight sur-

factants. In good approximation the interactions between the droplets can be described with a hard sphere potential. Contrarily to synthesized colloids, the interfacial properties of these droplets are reproducible and well defined. The size and shape can be systematically varied by changing the composition, temperature or concentration. For systems containing long chained surfactants, in the  $1\phi$  region the microemulsion forms spherical droplets at the *efb*. On the water-rich side of the respective phase diagram, the droplets turn to ellipsoidal aggregates and finally to network-like structures at the *ncb* with increasing temperature. At the *efb*, the droplets grow with increasing oil concentration, while an increase in the surfactant-to-water ratio increases the droplet density. Therefore, microemulsions can be regarded as easily adjustable model systems.

### 2.3.1. Phase Behavior

A variation in temperature, pressure and concentration yields several states of the ternary system whereas the pressure dependence is not considered in this work. The interested reader is referred to a review article by Schneider [250]. A phase prism [251] shows the different phases (see Fig.2.3). The corners of the phase prism represent the three components A, B and C, and the height is the temperature axis. White areas indicate  $1\phi$  regions,  $2\phi$  regions are indicated by tie lines and grey areas represent the  $3\phi$  region. The purple colored area characterizes a  $1\phi$  region wherein equal amounts of water and oil are solubilized [248].

The phase behavior of the ternary system is mainly determined by the three individual binary systems [252] which are represented by the side planes of the prism.

The oil-water system shows nearly for all mixing ratios a  $2\phi$  region and only in the high concentration regimes on the water- or on the oil-rich side, the low solubility of water in oil and vice versa allows small  $1\phi$  regions. The solubilities are slightly enhanced at higher temperatures but this is less important for the overall phase behavior of the ternary system.

An upper miscibility gap is found in the water-surfactant system with a lower critical point ( $cp_\beta$ ) at the temperature  $T_\beta$  [253]. Below this critical point, a  $1\phi$  region is observed due to the high miscibility of water and surfactant at low temperatures. The upper miscibility gap can be explained by a break of the hydrogen bonds. This upper loop shrinks with increasing hydrophilicity of the surfactant. A further lower miscibility gap of the binary

water-surfactant system is not considered in this work since it lies below the melting point [76].

In the binary oil-surfactant system, the miscibility of surfactant and oil is poor at low temperatures. A lower miscibility gap is found with an upper critical point ( $cp_\alpha$ ) at the temperature  $T_\alpha$ . At higher temperatures above  $T_\alpha$  a  $1\phi$  region exists due to the increasing hydrophobicity of the surfactant.  $T_\alpha$  is usually below zero for ternary H<sub>2</sub>O/oil/nonionic amphiphile systems [76].

In the ternary system, the critical points  $cp_\alpha$  and  $cp_\beta$  are start points of the critical lines  $cl_\alpha$  and  $cl_\beta$  in the phase prism (see Fig.2.3). The line  $cl_\beta$  starting from the water-surfactant plane decreases in temperature and ends at the lower temperature  $T_l$  at the critical endpoint  $cep_\beta$ . At  $T_l$  the surfactant-rich water phase separates into two phases, which are a microemulsion water phase and an oil excess phase. The  $cl_\alpha$ -line starting at the oil-surfactant plane develops towards higher temperatures and ends at an upper critical end point ( $cep_\alpha$ ) at  $T_u$  where the surfactant oil-rich phase separates into two phases: a microemulsion oil phase and a water excess phase. Thus, between  $T_l$  and  $T_u$  a  $3\phi$  region is formed which has the shape of a triangle (see grey colored area in Fig.2.3). Due to the increased hydrophobicity of the surfactant at higher temperatures at isothermal conditions, the surfactant is mainly dissolved in the oil phase at high temperatures. At lower temperatures, the surfactant becomes more hydrophilic and is mainly dissolved in the water phase. The shape of the  $3\phi$  triangle is then defined by the temperature dependence of the surfactant: At temperatures slightly above  $T_l$ , the composition of the middle microemulsion phase is shifted towards the water side and turns over to the oil side at higher temperatures. At  $T_l$  and  $T_u$  the  $3\phi$  triangle ends up in two critical tielines and merges into a  $\underline{2}$  and  $\bar{2}$  phase, respectively.

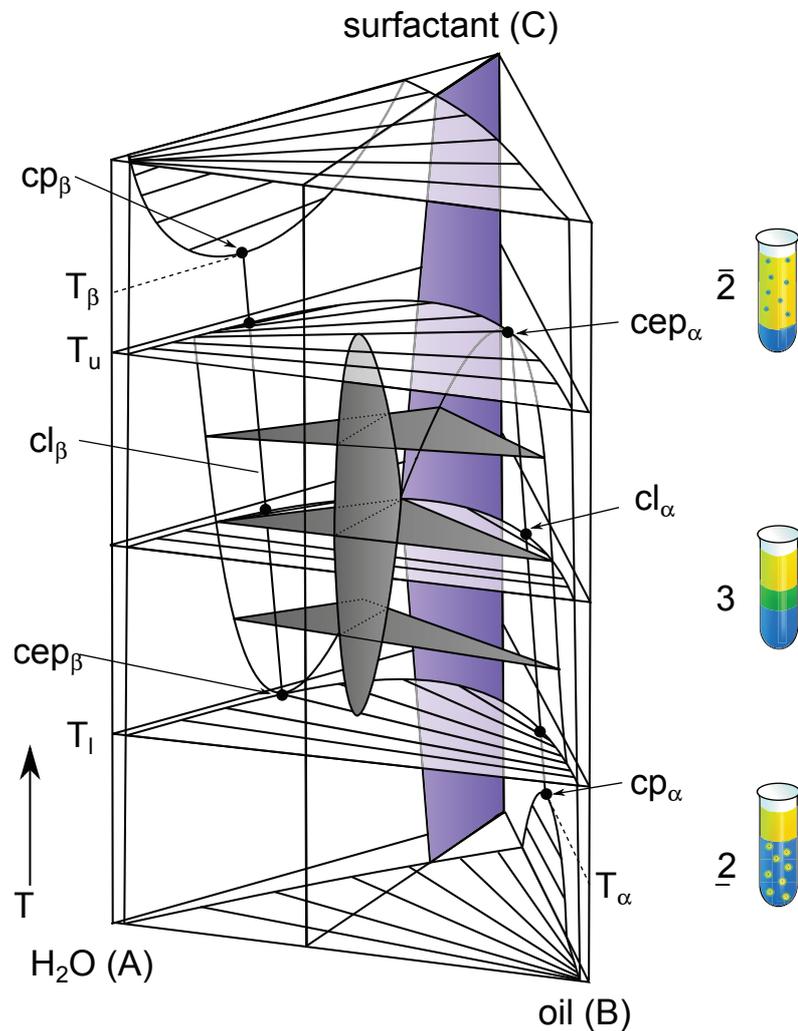

The individual concentrations are generally given in mass ratios, where

$$\gamma_a = \frac{m_C}{m_C + m_A} \quad (2.23)$$

gives the mass fraction of component C (mass of amphiphile,  $m_C$ ) in component A (mass of water,  $m_A$ ) and C. The mass fraction of component B (oil) is then given as ratio to the total mass of the system

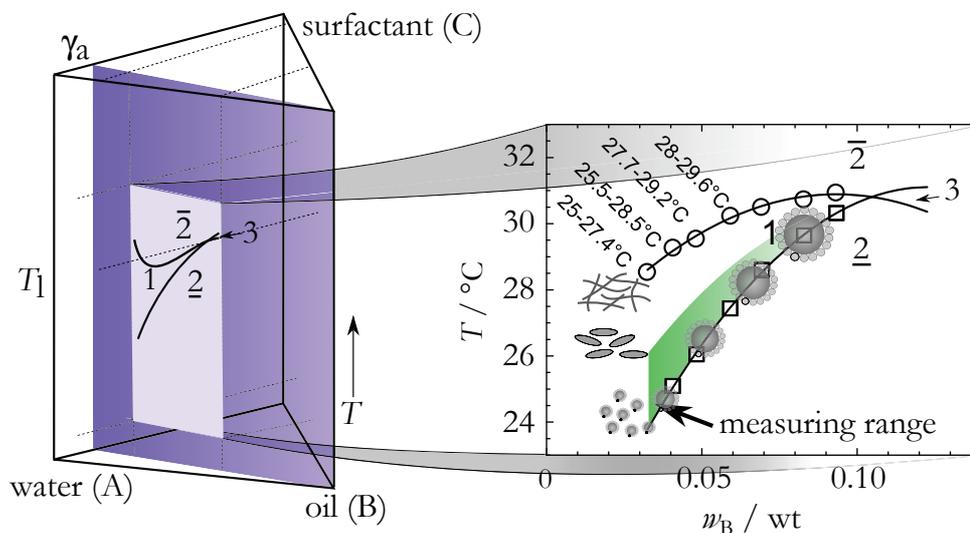

$$w_B = \frac{m_B}{m_A + m_B + m_C} \quad (2.24)$$

with the mass of the oil,  $m_B$ . In this work, we use *n*-alkanes as oil component and C<sub>12</sub>E<sub>5</sub>

**Figure 2.3.:** Typical phase prism of a microemulsion system consisting of water (A), oil (B) and surfactant (C). The temperature dependence is presented by the vertical of the prism. On the right side, different states are sketched: The lower  $2\phi$  region at low temperatures where the surfactant is dissolved in water with an coexisting oil excess phase, the middle  $3\phi$  region (grey) and the upper  $2\phi$  region where the surfactant is dissolved in the oil phase. The  $1\phi$  regime is colored in purple. The figure was redrawn from Strey [251].

as the amphiphile. At low surfactant concentrations and at certain temperatures, we find all three components dissolved in one phase ( $1\phi$ ). This  $1\phi$  equilibrium is classified as Winsor IV [254] and exists on the water-rich side and on the oil-rich side in the phase diagram [248] for low concentrations of oil and water, respectively. In this work we focus mainly on the investigation of the water-rich side of the phase prism (see Fig.2.4). Because the surfactant assembles at the water-oil interface, the surfactant film is curved around

**Figure 2.4.:** *Left:* Cut through the phase diagram of a ternary microemulsion system. Regions of constant  $\gamma_a$  are colored purple. Therein, temperature range and oil fraction span an area (light purple) in which we find a  $1\phi$  region, surrounded by an upper  $2\phi$  and a lower  $2\phi$  region. At higher oil concentrations, a  $3\phi$  region is observed. *Right:* On the water-rich side of a water/n-octane/ $C_{12}E_5$ , this  $1\phi$  region is observed close to room temperature. In the green area spherical microemulsion droplets are expected.

the oil and the system forms oil-swollen aggregates at low temperatures which are in the following referred to as oil-in-water (o/w) microemulsion droplets.

This region of o/w-droplets can be characterized by a cut through the phase prism in that way, that a temperature-oil mass fraction ( $T(w_B)$ ) dependence at constant  $\gamma_a$  is achieved (see Fig.2.4). The right part of Fig.2.4 sketches a  $1\phi$  region of the  $H_2O/C_8/C_{12}E_5$  system at constant  $\gamma_a = 0.022$  wt. The  $1\phi$  funnel is confined by two boundaries. The phase boundary at low temperatures is called emulsification failure boundary (*efb*), and at high temperatures the near critical boundary (*ncb*), respectively. The microemulsion aggregates form spherical droplets close to the *efb* [251,255] while with increasing temperature their shape changes to elongated aggregates and at the *ncb*, the aggregates form network-like structures [256–258] in the case of systems which contain long chain surfactants. The size of the microemulsion droplets at the *efb* increases with increasing oil concentration.

The goal of this work is the investigation of the thermal diffusion behavior of spherical microemulsion droplets of different sizes to determine the radial dependence of the Soret coefficient. Thus, the measurements are restricted to a temperature range close to the *efb* where these droplets remain spherical. Changes in the droplet shape with increasing

temperature limit the temperature range which is marked by the green colored area in Fig.2.4.

## EXPERIMENTAL SETUPS

This chapter describes the experimental setups which are used for the investigation of the binary sugar surfactant solutions and microemulsions and is structured as follows: The TDFRS technique is introduced and the setup is described by means of the IR-TDFRS setup in Sec.3.1.2. Recent improvements are discussed. In Sec.3.3, a report on the determination of the refractive index increment with concentration or temperature is given. For the latter one, a new setup was designed due to experimental difficulties caused by the high turbidity and strong scattering of the microemulsions. The advantages of this setup are outlined and a comparison to the ordinary  $(\partial n/\partial T)_{p,w}$  setup is given in Sec.3.3.4. Finally, the dynamic light scattering and the neutron scattering setup are introduced in Sec.3.2 and Sec.3.5, respectively. The latter setups are not in focus of this work but provide necessary information which complete findings obtained by TDFRS setups.

### **3.1. Thermal Diffusion Forced Rayleigh Scattering**

The Thermal Diffusion Forced Rayleigh Scattering (TDFRS) setup is a technique in which a small temperature gradient is created by an interference of two laser beams. The temperature difference is approximately 20-100  $\mu\text{K}$  and the fringe spacing is approximately 20  $\mu\text{m}$  which results in a thermal gradient of 1-5 K/m. This very small fringe spacing leads to measuring times in the range of milliseconds for low-molecular weight solutions [133] up to a few seconds for polymeric systems or macromolecules [259, 260].

Two setups are available: one setup, called classical TDFRS setup, uses a writing laser at 488 nm (Ar-laser, Innova 300C, Coherent, USA), and a second setup is working with an infrared laser at 980 nm (TA 100, Toptica Photonics AG, Germany), which is called IR-TDFRS setup. The latter setup is predestinated for aqueous systems while the classical TDFRS setup requires the addition of dye which leads to a sufficient absorption at the wavelength of the writing laser beams. The selected dye needs to be inert, so that it does not contribute to the signal or alters the system properties. This is in general easy to fulfill for organic systems, but in polar systems the dye changes its absorption properties with pH and can also change the phase behavior of complex systems [38].

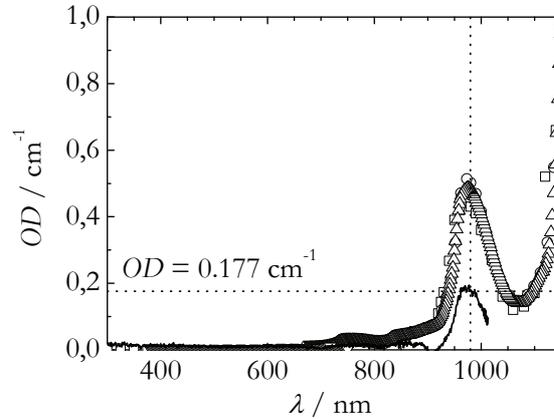

In the following, the TDFRS technique will be explained on the basis of the IR-TDFRS setup. The signal detection will be described in Sec.3.1.4. In the last two sections 3.1.5 and 3.1.6, the signal interpretation and analysis are discussed.

### 3.1.1. Absorption of Light in the IR-TDFRS Setup

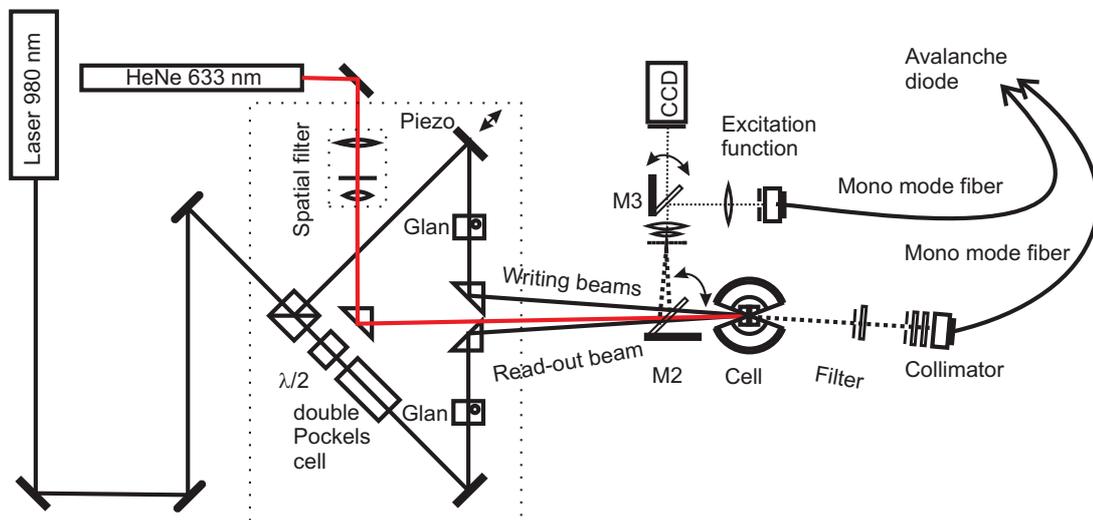

In this work we used mainly the IR-TDFRS setup to determine the thermal diffusion behavior of aqueous samples. The absorption of water at the writing laser wavelength is sufficiently high in the IR-TDFRS setup that the addition of dye is not needed. The wavelength dependent absorption of water was already determined by Hale and Querry [261], Palmer and Williams [262], Kou *et al.* [263] and Pope [264]. All groups determined an absorption between 0.43 and 0.52  $\text{cm}^{-1}$  at 980 nm. We perform absorption measurements using a Cary 50 spectrometer and find an absorption at this wavelength of 0.18  $\text{cm}^{-1}$ . Fig.3.1 shows the comparison of absorption spectra results and literature values. Independent from the differences in absorption values, the IR-laser provides sufficiently high power to write a thermal grating into aqueous samples.

### 3.1.2. Experimental Setup

The IR-TDFRS setup is sketched schematically in Fig.3.2. A vertically polarized laser beam at 980 nm is split into two beams of equal intensity by a beam splitter. One beam, in Fig.3.2 the lower one, passes a  $\lambda/2$ -plate which rotates the beam polarization from vertical to horizontal. A double Pockels cell is used to rotate the light polarization from horizontal to positive or negative vertical polarization by  $+90^\circ$  or  $-90^\circ$ , respectively. The Pockels cell is controlled by a high voltage amplifier (Leysop, England). The switching

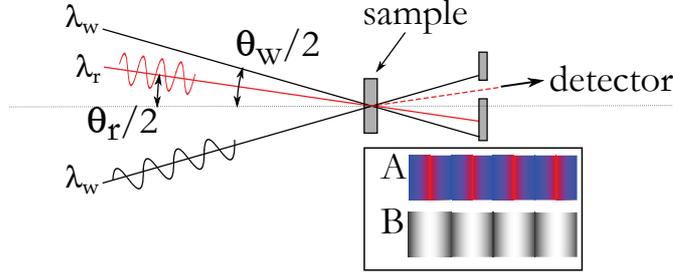

**Figure 3.1.:** The absorption of water in the wavelength range of visible light and near infrared. Absorption curves by Hale and Querry [261] (squares), Palmer and Williams [262] (circles), Kou et al. [263] (triangles up) and Pope [264] (triangles down) are compared with measurements performed for this thesis (solid line). The dotted lines are guides to the eyes and mark the absorption at 980 nm which is used in the IR-TDFRS to convert the intensity grating of the writing beams into a thermal grating.

**Figure 3.2.:** The IR-TDFRS setup is working at a wavelength of 980 nm (writing laser). A thermal grating is created by the absorption of the interfering IR-laser beams in the aqueous sample. The analysis of the time dependence of the diffracted red laser beam intensity yields the thermal diffusion parameters.

time is about  $10 \mu\text{s}$  and thus by a factor of ten faster than the fastest time process to be measured in this setup.

**Figure 3.3.:** The laser path ways in the IR-TDFRS setup. The dotted horizontal line is the symmetry axis, the solid lines are the IR-laser (black) and the HeNe-laser (red). The dashed line is the diffracted read-out beam. Inset: sinusoidal temperature (A) and refractive index (B) grating in the sample. In the warm regions (red), the refractive index is lower (white).

The upper beam in Fig.3.2, is reflected by a mirror which is mounted on a piezo crystal. By applying a voltage to the piezo, the position of the mirror can be changed. Thus, the path length of the beam is controlled and the phase difference to the first beam can be adjusted. Due to the limited coherence length of the laser, the optical path lengths of both writing beams are chosen to be equal. Glan-Thompson polarizers improve the quality of vertical polarization of both beams which interfere afterwards in the sample cell. The light intensity of the interference pattern is converted by absorption into a thermal grating. Due to the temperature dependence of the refractive index of liquids, the thermal grating induces a refractive index grating. Since the derivative of refractive index with temperature is always negative for liquids, the refractive index is higher in the colder regions of the temperature pattern, and lower in the warmer regions, respectively. A third read-out HeNe-laser beam at 632.8 nm (IR-TDFRS: Linos, Germany, Model HeNe 633-30P, 31 mW; class. TDFRS: Research Electro-Optics, Inc., USA, Model-No. 32413, 35 mW) is spatially filtered. The HeNe-laser probes the grating under the *Bragg* angle. The relative alignment to the writing laser beams satisfies the Bragg condition:

$$\frac{4\pi}{\lambda_r} \sin \frac{\theta_r}{2} = q_r \quad (3.1)$$

$$= q_w = \frac{4\pi}{\lambda_w} \sin \frac{\theta_w}{2} \quad (3.2)$$

where the indices  $r$  and  $w$  mark the read-out and writing beams with the wavelengths  $\lambda_r$  and  $\lambda_w$ , respectively.  $q$  is the scattering vector and  $\theta_r/2$  and  $\theta_w/2$  are the angles to the symmetry axis (see Fig.3.3).

Behind the sample an IR-filter blocks the IR-laser beams, while the intensity of the

diffracted HeNe-laser is detected by an avalanche diode (Model SPCM-AQRH-13-FC, PerkinElmer, Canada). The laser intensity, is adjusted by grey filters to match the optimal count rate range of the diode which is between 1 to 3 MHz. A typical normalized intensity signal in the IR-TDFRS setup versus time is shown in Fig.3.4. A detailed explanation of the signal curve is given in section 3.1.5.

The brass cell holder is temperature controlled by a water bath (E300, Lauda) with a stability of 0.1 K. The typical temperature range in the experiment is between 15 °C and 60 °C. A Pt100 sensor is mounted in the cell holder underneath the sample cell to measure the actual temperature. Apart from the front and back holes for the incoming and outgoing laser beams, the cell holder is completely closed to minimize heat loss to the environment. Flow cells by Hellma are used as sample cells with an optical path length of 0.2 mm. The front and back windows are made of quartz glass and are transparent for all laser beams.

Before the light beams pass the cell holder, a semitransparent mirror reflects approximately 1–2 % of the IR-laser beams through a microscope objective onto a camera to determine the fringe spacing of the interference pattern and therefore the  $q$ -vector. Between the semitransparent mirror and the camera a grey filter with an optical density of  $2.0 \text{ cm}^{-1}$  is mounted to reflect 1–2 % of the intensity onto a second avalanche diode. The grey filter is used to minimize ghost images due to internal reflections. The avalanche diode records the time dependence of the interference pattern (excitation function, see Sec.3.1.3).

The advantage of this setup, working with semitransparent mirrors to split the beam intensity onto both diodes and the camera, is the simultaneous determination of the excitation function and the diffracted signal from the sample. This feature was included into the setup recently. Beforehand the excitation function had to be measured separately which caused a longer overall measurement time. As the excitation functions had been measured at an earlier or later time, the experimental conditions changed slightly in the mean time.

### 3.1.3. Excitation Function

The mathematical derivation of the working equation (see Eq.3.8) assumes a step function as excitation function. In reality the build up of the high voltage is not infinitely steep but has a finite rising time of 10  $\mu\text{s}$ . In order to compensate for the delay and to account

for a slow change of the grating at long times, the build up of the pure intensity grating is recorded and its function is used to correct the measurement signal following a procedure by Wittko and Köhler [265]. A typical time dependence of the excitation function is shown in Fig.3.4 (dashed line), which is already normalized to the plateau value. The intensity signal starts at zero intensity and increases steeply within microseconds towards a plateau value which is reached after 10  $\mu$ s. This is a direct measure of the ability of the Pockels cell to shift the relative phase of the writing beams by 180°. The excitation function reaches the plateau when the phase shift is completed. For longer times, the intensity ideally remains constant in the plateau if voltage and phase are stable. Otherwise a decrease in the detected intensity is observed which is the case for long measuring times of slow diffusing systems ( $\tau_c \geq 5$  s) mainly due to temperature fluctuations along the separated optical paths of the two writing beams.

### 3.1.4. Heterodyne Signal Detection

Due to the interference of the writing laser beams a sinusoidal intensity grating is written in the sample, which is converted into a thermal grating by absorption. This grating causes a concentration grating due to thermodiffusion. Thermal and concentration grating induce a refractive index grating which is probed by a third read-out laser beam which does not alter the thermal grating. The intensity, which is detected by the avalanche diode (IR-TDFRS) or photomultiplier (classical TDFRS), can be described by the electrical field vectors of the diffracted beam,  $E_d$ , the coherent,  $E_c$ , and incoherent beam,  $E_{inc}$ , as [188]

$$I = |E_c + E_d e^{i\phi}|^2 + E_{inc}^2 = E_d^2 + 2E_c E_d \cos \phi + E_c^2 + E_{inc}^2 \quad (3.3)$$

whereas the homodyne intensity is  $I_{homo} = E_d^2$  and the heterodyne intensity is  $I_{het} = 2E_d E_c \cos \phi$ . The background intensity is  $I_b = E_c^2 + E_{inc}^2$  and  $\phi$  is the phase shift between the diffracted beam and the coherent background. Dust particles or scratches on the window of the sample cell generate the coherent background signal. Under standard conditions, we cannot distinguish between the heterodyne and homodyne signal contributions which is essential for the signal interpretation. One way to differentiate between both contributions is a phase modulation by  $\pi$ . Therefore, the Pockels cell shifts the phase of one of the writing beams by  $\pi$ . Thus, we obtain two intensities at the detector,  $I_{\phi+\pi}$

and  $I_\phi$ , for the  $\pi$ -shifted and the non-shifted beam, respectively,

$$I_{\phi+\pi} = |E_d e^{i(\phi+\pi)} + E_c|^2 + E_{inc}^2 \quad (3.4)$$

$$I_\phi = |E_d e^{i\phi} + E_c|^2 + E_{inc}^2. \quad (3.5)$$

The homodyne part of the intensity signal can be written as

$$\zeta_{homo} = \frac{1}{2} (I_\phi + I_{\phi+\pi}) - I_b \quad (3.6)$$

and the heterodyne part as

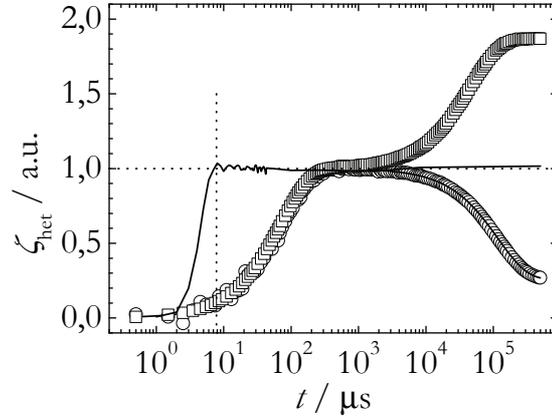

$$\zeta_{het} = \frac{1}{2} (I_\phi - I_{\phi+\pi}). \quad (3.7)$$

We measure the heterodyne intensity signal, because it is more robust than the homodyne signal [24]. Thereby, a maximization of the heterodyne signal contribution is achieved if the phase shift between coherent background and diffracted beam is zero. As we cannot control the phase of the coherent background, we control and stabilize the phase of the diffracted beam with the piezo mirror. A typical timing diagram is shown in reference [24]. For systems with equilibration times below 10 s the phase control with the piezo mirror is sufficient, but for slow diffusing systems, long term effects occur due to thermal fluctuations and diminish the contrast of the refractive index grating with time. Hence, the phase needs to be adjusted during the measurement. For this real-time phase tracking we analyze the interference grating with the camera, and vary the voltage applied to the piezo to achieve maximum contrast of the grating.

To improve the signal-to-noise ratio,  $I_\phi$  and  $I_{\phi+\pi}$  are averaged over time using several repetitions of the measurement (later referred to as runs). The phase is controlled every two or three minutes which is sufficient.

### 3.1.5. Signal Interpretation

Fig.3.4 sketches the time dependent normalized heterodyne signal which is measured through the sample (open symbols) and the corresponding signal of the excitation function (dashed line). All curves are normalized to the thermal plateau (horizontal dotted line). The excitation function reaches the plateau after 10  $\mu$ s and usually stays constant if no external disturbance declines the intensity grating and the voltage of the amplifier is stable. The intensity signal from the sample approaches the thermal plateau after approximately 80  $\mu$ s (vertical dotted line in Fig.3.4). During this time, the light inten-

**Figure 3.4.:** The normalized heterodyne intensity signal in the IR-TDFRS setup versus time. The sample is  $\text{C}_7\text{G}_1/\text{H}_2\text{O}$  with  $w = 0.069$  wt at  $20^\circ\text{C}$  (circles) and  $60^\circ\text{C}$  (squares). The horizontal dotted line is a guide to the eyes and marks the normalized thermal plateau. The excitation function (solid line) reaches the plateau after  $8 \mu\text{s}$  (vertical dotted line).

sity grating is converted into a thermal grating by light absorption of the sample. The thermal grating causes a refractive index grating. For liquids in general, the refractive index decreases with increasing temperature. This dependence is described by the partial derivative  $(\partial n / \partial T)_{p,w}$  at constant concentration and pressure. Thus, the refractive index shows a minimum at warmer regions and a maximum at colder regions, respectively. The read-out laser probes this grating. The detector measures the intensity of this diffraction peak.

Once, the thermal grating is established, it leads to a mass flux due to thermal diffusion. This second process is one or two orders of magnitudes slower than the first thermal process. This makes it possible to separate both processes. The mass flux causes an additional local change in refractive index. One has to distinguish between two cases: In one case, the component with the higher refractive index moves to the cold regions of the thermal profile. This amplifies the refractive index profile in the sample and the detected intensity increases with time. Otherwise, the component with the higher refractive index moves to the warm regions and the amplitude of the refractive index profile is lowered. Hence, the detected intensity decreases with time and the concentration plateau is found at lower intensities compared to the thermal plateau. Fig.3.4 shows both situations where the amplitude of the refractive index profile is amplified (squares) or diminished (circles) during the concentration process.

### 3.1.6. Signal Analysis

The time dependent heterodyne intensity signal,  $\zeta_{\text{het}}(t)$ , of the diffracted beam is described by an exponential fit function expressing the fast thermal process and the slow concentration process with the thermal time  $\tau_{\text{th}}$  and the equilibration time  $\tau_{\text{c}}$ , respectively, as

$$\zeta_{\text{het}}(t) = B \left\{ \left( 1 - e^{-\frac{t}{\tau_{\text{th}}}} \right) - \frac{A}{\tau_{\text{c}} - \tau_{\text{th}}} \cdot \left[ \tau_{\text{c}} \left( 1 - e^{-\frac{t}{\tau_{\text{c}}}} \right) - \tau_{\text{th}} \left( 1 - e^{-\frac{t}{\tau_{\text{th}}}} \right) \right] \right\} \quad (3.8)$$

with the scaling factor,  $B$ , and the amplitude of the second plateau,  $A$ , which relates to the Soret coefficient as

$$A = \left( \frac{\partial n}{\partial w} \right)_{p,T} \left( \frac{\partial n}{\partial T} \right)_{p,w}^{-1} w(1-w) S_{\text{T}} \quad (3.9)$$

with the concentration of the referring component of the mixture in equilibrium,  $w$ , the Soret coefficient,  $S_{\text{T}}$ , and the refractive index increment with temperature at constant pressure and concentration,  $(\partial n / \partial T)_{p,w}$ , or with concentration at constant pressure and temperature,  $(\partial n / \partial w)_{p,T}$ , respectively. The derivatives of the refractive index have to be determined in separate experiments (see Secs.3.3.1, 3.3.3 and 3.3.4). The refractive index increments are a measure to which extend the refractive index varies with temperature or concentration. These values are known as contrast factors.

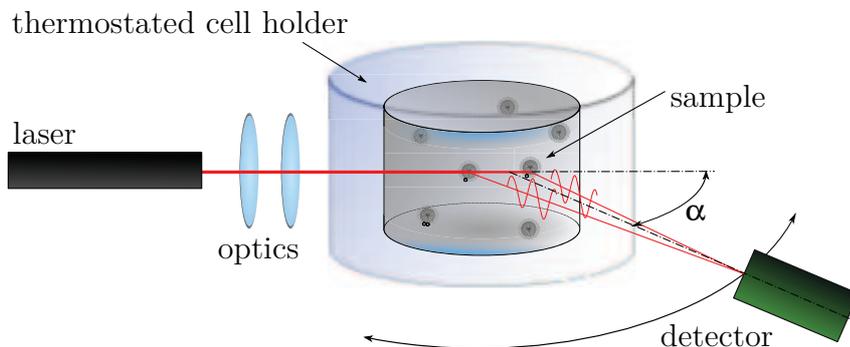

We obtain the mass diffusion coefficient

$$D = (\tau_{\text{c}} q^2)^{-1} \quad (3.10)$$

from the equilibration time of the concentration process,  $\tau_{\text{c}}$ , and the scattering vector,  $q$ . The thermal diffusion coefficient is calculated by Eq.2.22. Traditionally  $D_{\text{T}}$  can also be determined from the initial slope of the concentration part of the heterodyne intensity signal. We derive  $D_{\text{T}}$  by expressing Eq.3.8 as a Taylor expansion (see Appendix A). Hereby, the thermal diffusion coefficient is found as a linear factor in the first order term. Higher terms do not improve the expansion accuracy and are neglected.

## 3.2. Dynamic Light Scattering

Dynamic light scattering (*DLS*) is a well established method to determine the collective diffusion in a liquid mixture, solution or dispersion [266–271]. DLS is suitable to investi-

**Figure 3.5.:** Sketch of the dynamic light scattering setup. Incident light from a coherent laser is focused on the scattering volume. The inner sample (grey) is in thermal equilibrium with the surrounding toluene bath (blue) which is temperature controlled. The scattered light intensity is recorded by a detector which can be moved to measure at different angles. Due to Brownian motion, the scattered light intensity varies with time.

gate monodisperse particles or to determine the size distribution of polydisperse samples. The detectable particle size is in the range of some nanometers up to a micron in diameter. The lower range is limited due to the operating speed of the correlator and detectors. For larger particles the DLS technique is not feasible due to the sedimentation of the particles unless they are density matched.

One of the main disadvantages of the DLS method is the determination of the hydrodynamic radius which is the equivalent of a sphere with the same radius. This is not always directly related to the shape or rigidity of the measured solute particles, but also influenced by interactions with the solvent and between the particles. Later investigations of microemulsion droplets (chapter 6) requires the knowledge of the radius of gyration, which is a better measure of the shape of the solute particles. For that purpose, we additionally employ neutron scattering experiments as briefly described in Sec. 3.5.

In the following, the experimental setup is explained and the data analysis is described under the assumption of monodisperse samples. Later, we will also discuss the polydispersity of systems, which have been investigated in this work.

### 3.2.1. Principle

A cylindrical sample cell is mounted in a thermostated toluene bath. On the one hand, the toluene bath provides a precise temperature control with a stability of 0.1 K (Lauda E300 thermostat) and on the other hand it reduces scattering from the sample cell surfaces.

The time dependent intensity of scattered light from a monochromatic and coherent light source (HeNe-laser at 632.8 nm) of the dissolved particles in the scattering volume is detected. The scattering intensity depends on the size of the particles and the scattering angle. The latter one is varied in a range from  $30^\circ$ , which is close to forward scattering, to  $150^\circ$  close to backscattering. The incident light is scattered by particles or concentration fluctuations. Destructive and constructive interference leads to a fluctuating intensity. The time-intensity-correlation function,  $g_2(\tau)$ , is a measure for the similarity of two scattering states at different times and is described as the averaged sum of the products of the intensities  $I(t)$  and  $I(t + \tau)$  at times  $t$  and  $t + \tau$ , respectively, at different delay times  $\tau$ ,

$$g_2(\tau) = \langle I(t) \cdot I(t + \tau) \rangle = \frac{1}{t_{total}} \int_0^{t_{total}} I(t) \cdot I(t + \tau) dt. \quad (3.11)$$

$g_2(t)$  can be expressed with the normalized field-time correlation function,  $g_1(\tau)$ , (see Fig.3.6) by the Siegert-relation

$$g_2(\tau) = B_1 + \beta (g_1(\tau))^2, \quad (3.12)$$

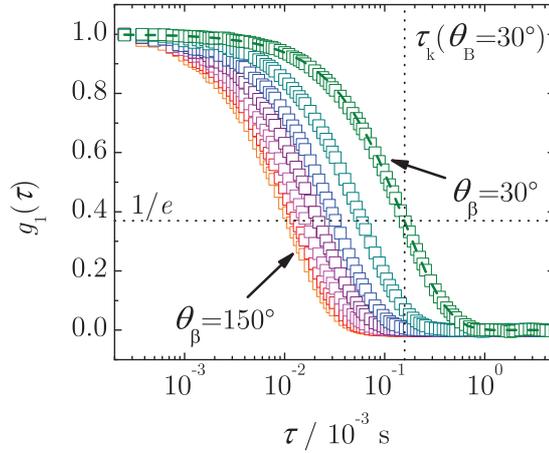

where  $B_1$  and  $\beta$  are dimensionless instrument factors.  $g_1(\tau)$  can be expressed with to

$$g_1(\tau) = e^{-\Gamma\tau} = e^{-q^2 D\tau} \quad (3.13)$$

with the decay rate,  $\Gamma$ , and the translational diffusion coefficient,  $D$ . The decay rate is calculated from the correlation function which is in turn fitted by a single exponential function for monodisperse suspensions. Another fit function is a stretched exponential function, the so called Kohlrausch-Williams-Watts (KWW):

$$\varphi_{KWW}(\tau) = e^{-(\tau\Gamma)_{KWW}^\beta} \quad (3.14)$$

with the fit parameter  $\beta_{KWW}$ . A fit of Eq.3.14 on one of the correlation functions, which was measured at a scattering angle of  $30^\circ$ , is drawn as a dashed line in Fig.3.6. This general writing of the KWW function is used in a wide scientific range working with relaxation dynamics or exponential stress decay processes [272, 273]. The translational diffusion coefficient is the linear slope of the  $\Gamma(q^2)$ -plot. A typical dependence of the decay rate on the squared scattering angle is shown in Fig.3.7 for an aqueous surfactant solution containing 0.021 wt C<sub>8</sub>G<sub>1</sub> at 20 °C and 30 °C and scattering angles between  $30^\circ$  and  $150^\circ$ .

**Figure 3.6.:** Correlation signal of a 0.021 wt  $C_8G_1/H_2O$  mixture at  $T = 20\text{ }^\circ\text{C}$ . A single exponential KWW-function (dashed line) was fitted to the data points (open circles). The vertical dotted line marks the correlation time obtained by KWW-fit.

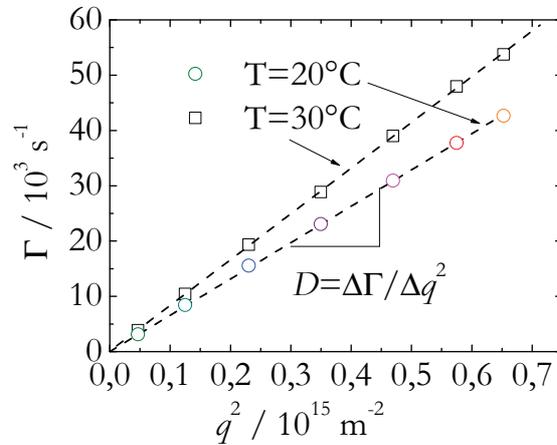

The Stokes-Einstein-Equation is used to calculate the hydrodynamic radius  $r_H$ ,

$$r_H = \frac{k_B T}{6\pi\eta D} \quad (3.15)$$

with the Boltzmann constant,  $k_B$ , the temperature,  $T$ , and  $\eta$  is the viscosity of the solvent which is approximately equal to the viscosity of the pure solvent at the respective temperature and concentration. Eq.3.15 can only be used, if the mixture is sufficiently high diluted and far away from critical points ( $r_H \cdot \theta \ll 1$ ). At higher concentrations the collective diffusion coefficient is measured and not the self-diffusion coefficient and the Brownian theory cannot be applied for the calculation of the hydrodynamic radius [274].

Hence, the hydrodynamic radii of the exemplary investigated surfactant micelles in Figs.3.6 and 3.7, are calculated to  $r_H = (3.19 \pm 0.33)$  nm at  $20\text{ }^\circ\text{C}$  and to  $r_H = (3.35 \pm 0.15)$  nm at  $30\text{ }^\circ\text{C}$ . A more detailed discussion of the concentration and temperature dependence of the micellar systems is given in Sec.2.2.1. Due to the small size of the micelles, it is not possible to obtain further details about the shape. This would require SANS measurements.

Up to this point, the latter discussion was based on the assumption of monodisperse samples. However, for polydisperse particles, Eq.3.13 is not usable, as multiple decay times occur in the correlation function. In that case,  $g_1(\tau)$  is expressed as a sum of several weighted decay terms, or as a continuous distribution function which is often determined with the (*CONTIN*) program [275, 276]. For microemulsions close to the emulsification

**Figure 3.7.:** The decay rate versus the squared wave vector for different scattering angles at 20 °C (circles) and 30 °C (squares). The diffusion coefficient is given as the linear slope (dashed line). The sample is  $\text{C}_8\text{G}_1/\text{H}_2\text{O}$  with a weight fraction of 0.021 wt.

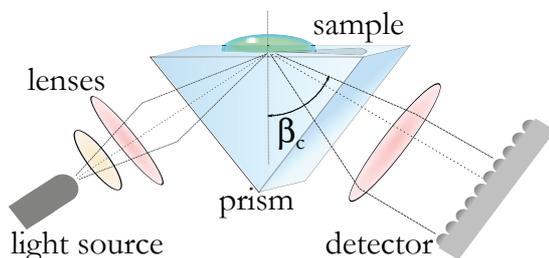

failure boundary, CONTIN yields a narrow size distribution while at higher temperatures, CONTIN predicts a wider size distribution [277]. In this case, the most probable size is taken for further calculations.

### 3.3. Refractive Index

As discussed in Eqs.3.9 the determination of the thermal diffusion coefficient and the Soret coefficient requires the measurement of the refractive index increments. In the following, the experimental setups are introduced which determine the absolute refractive index by critical angle determination in Sec.3.3.1 or the increment of the refractive index with temperature using the change of optical path length in a medium due to temperature changes in Sec.3.3.3 and Sec.3.3.4.

#### 3.3.1. Refractometer

We use a refractometer from Anton Paar (Abbemat RXA 156), working with a synthetic sapphire prism at a wavelength of 589.1 nm (Na-D line) as it is shown in Fig.3.8. In this machine, a 2048 pixel array is used to measure the intensity of refracted light. The critical angle, where the intensity curve shows a pronounced bend, is determined automatically

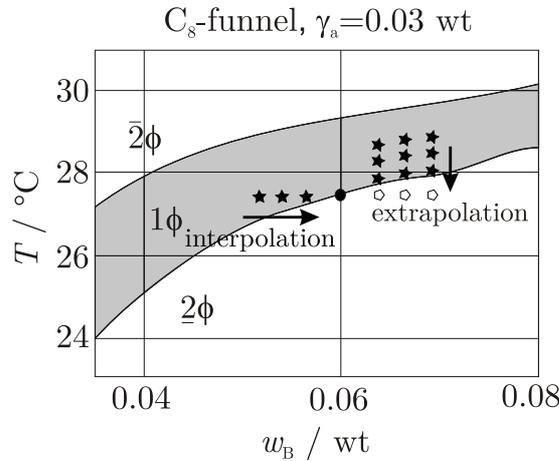

**Figure 3.8.:** Sketch of the Abbe refractometer: At the interface between the solution (green) and the prism (blue) light from a diode (dark grey) is refracted. Beforehand, the emitted light is filtered (yellow) and focused (red lens). A pixel array (light grey) detects the angle-dependent light intensity.  $\beta_c$  is the angle of refraction at the critical point where total internal reflection occurs.

by the instrument. The prism is temperature controlled by a Peltier thermostat with a temperature stability of 0.03 K in a range between 10 °C and 70 °C. A high-power LED is used as light source and the Na-D line is selected by an interference filter yielding a wavelength error of 0.1 nm. The error of the refractive index value is  $2 \cdot 10^{-5}$ .

### 3.3.2. $(\partial n/\partial w)_{p,T}$ -Determination at Phase Transition Boundaries

The determination of the refractive index derivative with concentration is in general a fast and precise method. We use the refractometer from Anton Paar (see Sec.3.3.1) and measure the refractive index at constant temperature for different concentrations which are slightly lower or higher than the actual concentration ( $\pm 10\%$ ). By that, we determine the slope of the refractive index with respect to concentration for constant pressure and temperature at the desired concentration. The measurement of the refractive index requires homogeneous samples. Therefore, special care needs to be taken if microemulsions are investigated, because due to evaporation the concentration can change, which might lead to a phase separation. Also a change in temperature might bring the system from the  $1\phi$  region into a  $2\phi$  region as it is sketched in Fig.3.9. The main problem in  $2\phi$  is that the composition of the microemulsion changes locally if a second phase occurs (see Sec.2.3.1). This leads also to an inhomogeneous refractive index, which makes a measurement of the refractive index increment unreliable. The refractive indices of the lower concentrations can be directly measured, because they lie in the  $1\phi$  region (solid stars in Fig.3.9). In order to obtain the refractive index increments of a specific concentration, the refractive indices at higher concentrations need to be extrapolated from the  $1\phi$  region (pentagons in

**Figure 3.9.:** Determination of the refractive index derivative with concentration for microemulsion systems in the  $1\phi$  phase (grey area). The solid circle marks the desired concentration at which the refractive index increment with concentration is determined. Therefore, the directly measurable concentrations (filled stars) and the extrapolated data points (white pentagons) are used. The pentagons are determined by extrapolating from higher temperatures in  $1\phi$ .

Fig.3.9). The directly measured and extrapolated refractive indices are used to determine the  $(\partial n / \partial w)_{p,T}$ -value at the desired concentration (circle in Fig.3.9).

The extrapolation to the data points in  $2\phi$  region needs a sufficient large temperature range in  $1\phi$  region. At least three different temperatures are measured. Generally temperatures in the lower third of the  $1\phi$  funnel close to the *efb* are taken, because network-like structures are formed above. The phase diagrams of nonionic microemulsions show that the funnel shrinks in temperature with increasing oil concentration (Sec.2.3.1). If the temperature range becomes too narrow to perform reliable refractive index measurements in the  $1\phi$  region, we do not measure at higher concentrations and only take refractive index values from lower concentrations into consideration to determine the slope.

### 3.3.3. Michelson Interferometer

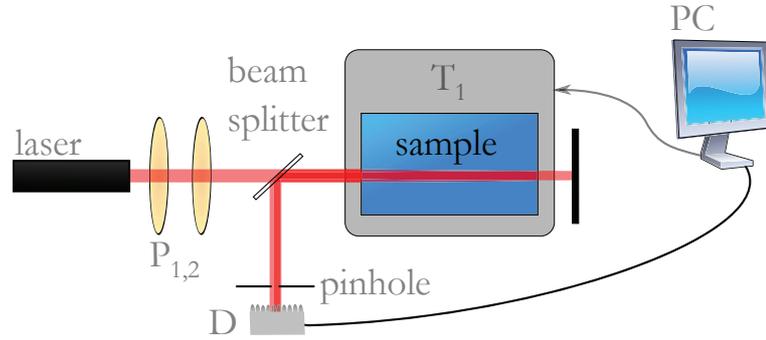

In this section, the main principle of the  $(\partial n / \partial T)_{p,w}$  determination is discussed. For this purpose we use a Michelson interferometer [265] as shown in Fig.3.10. Later, an improved interferometric setup will be introduced in section 3.3.4.

A HeNe-laser (5 mW at 632.8 nm, Type 25-LHP-151-230, Melles Griot, USA) beam, which intensity is controlled by two polarizers ( $P_{1,2}$ ), passes a beam splitter and is partially

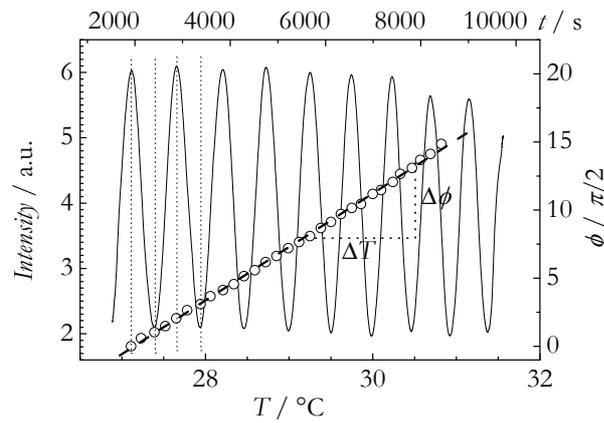

reflected at the surfaces of the sample cell (Hellma, Germany, optical path length: 10 mm). The sample cell is in thermal equilibrium with a brass cell holder ( $T_1$ ) which is thermally insulated from the environment and temperature controlled by a thermal bath (Lauda E300) with a temperature stability of 0.1 K. The thermal fluctuations inside the sample holder are sufficient low and the temperature is determined by a Pt100 sensor which is connected with a computer. The computer sets the bath temperature and records data during the measurement.

There are four reflections when the laser beam passes the sample cell at the air-glass interfaces and the glass-sample interfaces at the front and at the back side of the cell. The major part of the beam intensity is reflected at the interfaces of higher refractive index difference, which are the air-glass interfaces. Hence, mainly those two reflected beams interfere at the detector, because the front and the back windows are never perfectly parallel. In front of the detector a pinhole of less than 1 mm in diameter detects only a small area of the interference pattern. As the reflected beam from the back window passes the sample twice its intensity will be for a turbid sample much lower than the intensity of the beam reflected at the front window. The optical path length through the sample depends on the refractive index which changes due to a temperature change. A variation in temperature causes a phase modulation of the beam which passes through the sample. Meanwhile the phase remains nearly constant for the primarily reflected beam. The relative phase shift between both beams in turn causes a shift of the interference pattern. By changing the temperature continuously, the interference pattern *moves* which induces a sinusoidal intensity at the photo diode. With an applied temperature gradient of 0.5 K/s, the detected intensity versus time or temperature, respectively, is shown as a black line in Fig.3.11.

We start the measurement at a temperature  $T_{start}$  and wait for one hour for thermal equilibration of the sample. Special attention has to be paid to the microemulsion samples, for which the cell, the cell holder, and the microemulsion have to be thermostated before filling to ensure that the sample is in the  $1\phi$  region and stays there during the measurement. Afterwards, we vary the temperature continuously with time until we reach the end temperature  $T_{stop}$ . The applied temperature gradient is in the range of 0.5 mK/s to 1 mK/s and small enough to have the system all time thermally equilibrated. During the measurement, the refractive index is decreasing ( $T_{stop} > T_{start}$ ) or increasing ( $T_{stop} < T_{start}$ ) as the derivative of refractive index with temperature is negative for liquids. Fig.3.11 shows the time dependence of the recorded intensity. The results have been obtained for a microemulsion of  $H_2O/C_{10}/C_{12}E_5$ , ( $\gamma_a = 0.03$  wt,  $w_B = 0.029$  wt).

**Figure 3.10.:** Sketch of the Michelson interferometer.  $P_{1,2}$  are polarizers,  $T_1$  is the thermostated brass cell holder. The computer records data from the photo diode ( $D$ ) and controls the temperature of the cell holder.

**Figure 3.11.:** The detected intensity in the Michelson interferometer versus temperature. The temperature gradient is  $0.5 \text{ K/s}$ . A microemulsion is used ( $\text{H}_2\text{O}/\text{C}_{10}/\text{C}_{12}\text{E}_5$ ,  $\gamma_a = 0.03 \text{ wt}$ ,  $w_B = 0.029 \text{ wt}$ ). The periodicity in terms of  $\pi/2$  versus temperature (open circles) is fitted linearly (dashed line) and the vertically dotted lines are guides to the eyes and mark the  $\pi$ -steps of the intensity function. The slope  $\partial\phi/\partial T$  (dashed line) is required in Eq.3.16.

The refractive index increment can be calculated with [265]

$$\left(\frac{\partial n}{\partial T}\right)_{p,w} = \frac{\lambda}{4\pi l} \left(\frac{\partial \phi}{\partial T}\right)_{p,w} \underbrace{-2\frac{n_w}{l} \left(\frac{\partial l_w}{\partial T}\right)_{p,w}}_{\approx -1.86 \cdot 10^{-7}} \underbrace{-2\frac{l_w}{l} \left(\frac{\partial n_w}{\partial T}\right)_{p,w}}_{=-2.45 \cdot 10^{-6}} \underbrace{-\frac{n}{l} \left(\frac{\partial l}{\partial T}\right)_{p,w}}_{\approx 1.13 \cdot 10^{-6}}. \quad (3.16)$$

The first term accounts to the phase change with temperature in the sample cell, the second term accounts for the thermal expansion of the cell windows, the third term is

deduced from the changes of the refractive index of the cell windows due to temperature changes and term four relates to the length expansion of the sample cell with temperature. Parameters are the refractive index of the window,  $n_w = 1.457$ , the thermal expansion coefficient of the front and back windows,  $\alpha_w = 5.1 \cdot 10^{-7}$ , the thermal expansion coefficient of the cell surfaces parallel to the beam,  $\alpha_s = 7.5 \cdot 10^{-7}$ , the wavelength of the HeNe-laser,  $\lambda$ , the optical length of the absorption cell,  $l$ , the optical window thickness,  $l_w$ , and the periodicity of the intensity function,  $\phi$ . Typical values for the characteristic terms of the material properties are given below the equation.

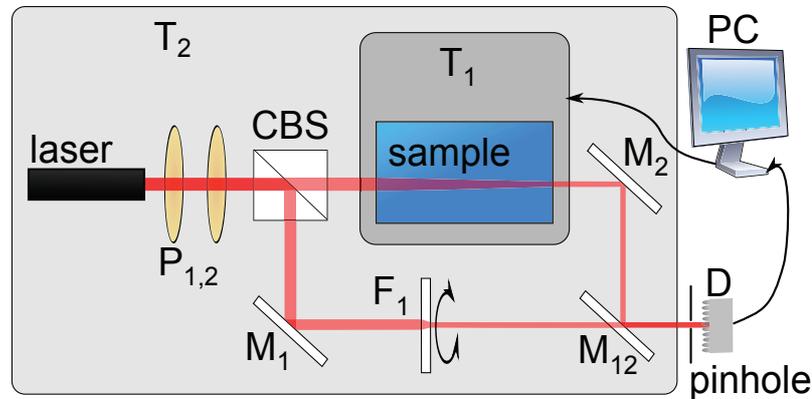

### 3.3.4. Improvements of the Michelson Interferometer

The advantages of the previously described Michelson interferometer are clear. The setup is compact and thermal fluctuations of the phases are small. One beam passes the absorption cell twice which doubles the investigated optical path length through the sample volume, but this leads to problems for turbid samples.

Technical difficulties arise from the geometry of the cell. The angle of the front and back windows to the laser beam have to be within a tolerance to permit interference. In the standard setup also the number of interfaces for both beams is different. The reflected beam from the back window has to pass seven interfaces while the reflected beam from the front window only passes one interface. The intensity of the laser beam which passes the sample twice, can be reduced by an order of magnitude and more, if the turbidity of the sample is high. This leads to a very weak intensity modulation which can not be analyzed.

We constructed a new Michelson interferometer for the measurement of strong scattering and turbid samples. Additionally, the new setup does not suffer from the sample cell geometry. At the same time, the main advantages of the previous setup are kept. A sketch is shown in Fig.3.12. The whole setup is aligned on an optical breadboard to avoid mechanical vibrations. The laser beam (HeNe-laser, Polytec, Type PL-750P, 5 mW at 632.8 nm) is split by a beamsplitter cube in two beams of equal intensity. The reference beam is directed through a continuous grey filter wheel ( $F_1$ ) onto a photodiode (D), while the measuring beam passes the temperature controlled sample cell and is superimposed to the reference beam by a semi-transparent mirror ( $M_{12}$ ) with a transmission of 50 %. The sample cell and the cell holder are identical to the standard interferometric setup.

The main problem of the construction is that the total path length of the separate beams is

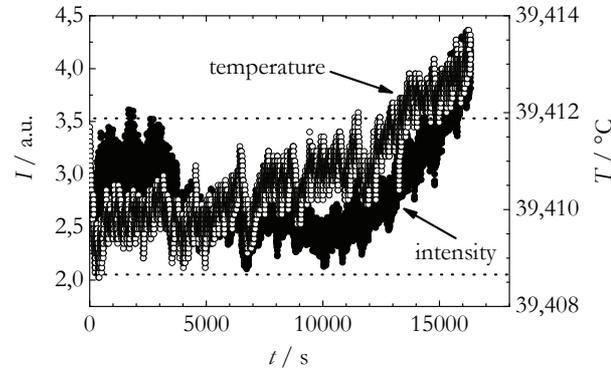

**Figure 3.12.:** Sketch of the improved Michelson interferometer, optimized for strong scattering or turbid samples.  $P_{1,2}$  are polarizers,  $D$  is the photo diode and CBS is the beamsplitter cube,  $T_1$  is the temperature controlled brass cell holder and  $T_2$  is the thermally insulating box surrounding the interferometer. The mirrors are  $M_1$ ,  $M_2$  (no transparency) and  $M_{12}$  (50% transparency).  $F_1$  is the continuous grey filter wheel to match the intensities of both beams.  $D$  is the photo diode. The computer records the data from the diode and controls the temperature of the cell holder.

about 40 cm. Perturbing effects such as temperature fluctuations have to be minimized as they disturb the optical path length measurement. Therefore, the cell holder is thermally insulated in a box  $T_1$  and the entire setup is surrounded by a box  $T_2$ , whereas the laboratory is air conditioned and the room temperature is kept constant with a stability of  $\pm 1$  K. The mechanical effects due to vibrations of the building are sufficiently blocked by the optical breadboard. It should be mentioned, that the path length difference of both beams is less than 1 cm and smaller than the coherence length of the HeNe-laser so that we satisfy the conditions for interference.

The interference pattern is optimized by adjusting the intensity of the reference beam to the same intensity level as the measuring beam (which passes the sample cell) with the continuous grey filter. Additionally, both intensities are reduced by the polarizers to a level that the photodiode responds linearly. A power meter (fieldmaster, Coherent, USA, discrepancy of 2% at 632.8 nm) is used to adjust the beam intensities. Finally, the semitransparent mirror  $M_{12}$  and the mirror  $M_1$  are used to align both beams onto the photodiode.

Thermal as well as mechanical fluctuations can never be suppressed completely. To determine the strength of present fluctuations, we perform test measurements with pure water in a temperature range between 37 °C and 43 °C to determine the contrast of the

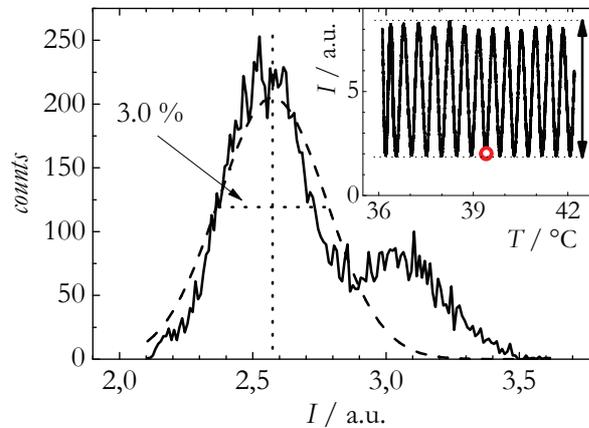

**Figure 3.13.:** Intensity (filled symbols) and temperature (open symbols) versus time of water. The dotted lines mark the range used for the error calculation.

measurement. The inset of Fig.3.14 shows the recorded sinusoidal intensity versus temperature. The full amplitude of the signal is 6.57 in arbitrary units. Then in a second measurement, the temperature was kept constant at 40.00 °C in the water bath. Due to a loss of heat in the water cycle, the real temperature was approximately 39.41 °C. After an equilibration time of 60 minutes, the intensity and temperature were recorded for four hours (Fig.3.13). Assuming a perfect measurement, no change in temperature should occur, but an increase in the detected intensity indicates that the temperature was not constant. It is assumed that the room temperature changed.

The distribution of data points versus intensity is fitted by a Gaussian distribution using

$$y(I) = y_0 + \frac{\sigma}{\sigma\sqrt{2\pi}} e^{-\frac{1}{2}\left(\frac{I-\mu}{\sigma}\right)^2} \quad (3.17)$$

with the standard deviation,  $\sigma$ , the expectation,  $\mu$ , and the offset,  $y_0$ . It is assumed, that  $y_0 = 0$ . The Gaussian fit is plotted as a dashed line in Fig.3.14. Deviations occur at higher intensities ( $I > 2.9$ ) due to the influence of the room temperature. The Gauss distribution shows a main peak at 2.57 (vertical dotted line) and the full width at half maximum is calculated to  $\Delta I = 0.20$  (horizontal dotted line) or 3.0 % regarding the previously determined intensity range of 6.57. This value is taken as a statistic error of the setup.

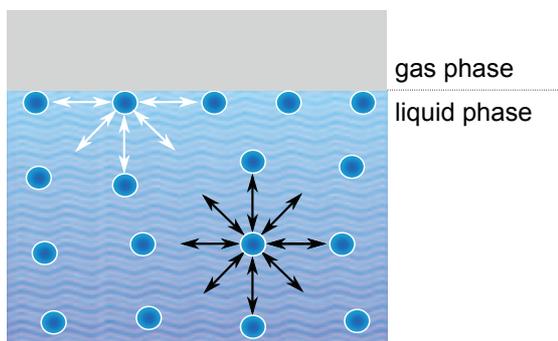

**Figure 3.14.:** The intensity distribution (solid line) is fitted with a Gaussian function (dashed line). The full width at half maximum is given as a dotted line. The systematic error is approximately 3.0%. Inset:  $(\partial n / \partial T)_{p,w}$ -measurement of pure water in temperature variation from 37 °C to 43 °C to determine the achievable minimum and maximum intensities (horizontal dotted lines). The circle marks the temperature at which data from Fig. 3.13 were recorded.

### 3.4. Surface Tension Measurements

One goal of this work was the determination of the thermal diffusion behavior of aqueous surfactant solutions close to the *cmc*. For the determination of the *cmc*, surface tension measurements have been performed in Köln. Concentration series at different temperatures have been measured for each surfactant. Then, the *cmc* is determined as the concentration, where the surface tension turns from a concentration dependence to an independent behavior.

In general, surface tension is a property of a fluid surface to resist against external forces. It is caused by molecular attraction forces between molecules in the interface to a fluid or gas phase. In the liquid phase, intermolecular cohesion forces are homogeneously distributed and each molecule attracts neighbor molecules. Hence, the total force on a molecule in the liquid phase is zero. Contrarily, in the interface the attraction forces between the molecules are spatial inhomogeneously distributed since there are no more neighbor molecules in the gas phase and the total force points perpendicular to the surface into the bulk (Fig. 3.15). Thus, the driving forces push surface molecules into the liquid phase to minimize binding energy. On the other hand, energy is needed to bring a molecule

**Figure 3.15.:** Intermolecular attraction forces are sketched in the fluid phase (blue) and in the surface layer to the gas phase (grey). The circles sketch water molecules. The total force is zero for molecules in the liquid phase (black arrows), while it is directed perpendicular to the surface area for molecules in the surface layer.

into the interface as bonds to surrounding molecules have to be broken. Accordingly, a reduction of surface area comes along with a gain in energy.

Then, the surface tension,  $\sigma$ , is given as the ratio of required energy (or work),  $\Delta W$ , which is needed to enlarge the surface area by  $\Delta A$ :

$$\sigma = \frac{\Delta W}{\Delta A}. \quad (3.18)$$

This work is equal to the change of the Gibbs free energy and the surface tension is defined by

$$\sigma = \left( \frac{\partial G}{\partial A} \right)_{T,p} \quad (3.19)$$

with the Gibbs free energy,  $G$ , the area,  $A$ , and  $\partial/\partial A$  is the partial derivative with the area at constant temperature and pressure.

The surface tension can be decreased by increasing the temperature or by adding a surface active component. We used nonionic sugar surfactants. The surfactants have a hydrophobic carbon chain of different length and one or several hydrophilic sugar rings as head group. These amphiphilic molecules prefer to go into the air-liquid interface. The surface tension decreases with increasing surfactant concentration. At a certain concentration, the surface is saturated with surfactant molecules. This concentration is called the critical micelle concentration ( $cmc$ ). Above this concentration, the surfactant molecules will aggregate in the liquid. It is energetically favorable to screen the carbon chains from water: micelles are formed, wherein the hydrophobic chain is found in the inner micellar core and the hydrophilic surfactant head group is in contact with the aqueous solvent

in the micellar shell. Also single surfactant molecules are dissolved in the solvent and molecular exchange occurs between the micelles and the free surfactant molecules in the liquid or in the surface layer, respectively. The micellar shape and structure depend on the hydrophilicity of the surfactant head group whereas the *cmc* strongly depends on the hydrophobicity of the surfactant carbon chain which generally initiates the formation of micelles (see Sec. 2.2.1).

In the following, the concentration dependence of the surface tension is used to determine the *cmc* (see Sec.3.4.1). As a variation in temperature can also induce the formation of micelles, the respective temperature is called critical micelle temperature (*cmt*). In the following, the experimental method is briefly discussed and the working equations to determine the critical micelle concentration are introduced.

### 3.4.1. Setup

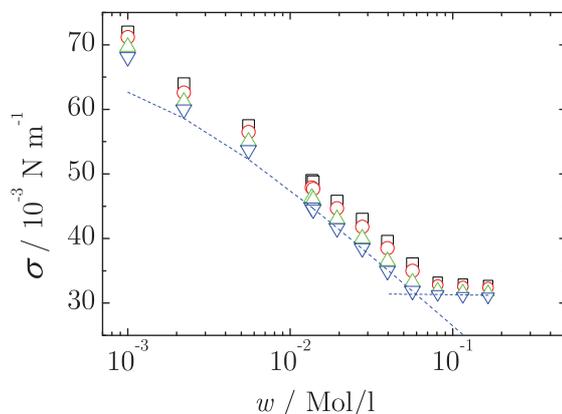

Several methods are known to measure the surface tension of a liquid-gas [278] or liquid-solid interface [279–281]. We perform the measurements in Köln with a Krüss digital tensiometer K10T using the Du-Nouÿ ring method [282–284]. A ring, dipped in the liquid phase, is pulled out of the phase. The surface tension causes the liquid film to stick to the ring. By pulling the ring out of the liquid phase, this film is stretched. The maximum force, which is required to stretch the film before the ring loses contact, is measured.

The temperature in the tensiometer is kept constant with a stability of  $\pm 0.1$  K within the measuring range between 15 °C and 40 °C. We perform concentration series starting at highest concentration and dilute the mixture stepwise. Before each measurement, we wait until the mixture is in equilibrium and the surface tension is constant for 90 minutes. This equilibration time was also used by Inoue *et al.* [285] for aqueous solutions of polyoxyethylene oleyl and polyoxyethylene stearyl. The concentration series is measured at constant temperature. The surface tension of pure water is taken as the lowest concentration value.

### 3.4.2. Theory

The experimentally determined surface tension  $\sigma^{exp}$  has to be corrected for finite wall effects [286] by

$$\sigma = 1.07\sigma^{exp}F \quad (3.20)$$

**Figure 3.16.:** The surface tension of  $C_7G_1/H_2O$  at temperatures: 15 °C (squares), 20 °C (circles), 30 °C (triangles up), and 40 °C (triangles down). For  $T = 40$  °C (triangles down), the dashed lines represent the fits: Eq.3.22 is applied in the low concentration regime while a linear fit was used to fit higher concentrations.

where  $F$  is the correction factor [287]

$$F = 0.725 + \sqrt{0.4036 \cdot 10^{-3} \frac{\sigma^{exp}}{\rho_{mix}^0 - \rho_{air}^0} + 0.0128} \quad (3.21)$$

with the macroscopic densities  $\rho_{air}^0$  and  $\rho_{mix}^0$  of air and the mixture, respectively. The corrected surface tension values from Eq.3.20 versus concentration are fitted using a linear regression for  $w > cmc$ , and the Langmuir-Szyszkowski equation [288] for  $w < cmc$ :

$$\sigma = \sigma_0 - a \ln(bw + 1) \quad (3.22)$$

with the surfactant concentration,  $w$ , and the fit parameters  $a$  and  $b$ . At the lowest concentration, the Langmuir-Szyszkowski equation deviates but close to the intersection point, Eq.3.22 describes the data at 40 °C accurately and the intersection of both fits provides the  $cmc$ . Fig.3.16 shows the surface tension versus the logarithmic concentration for the aqueous  $C_7G_1$  system at several temperatures. The surface tension decreases with increasing temperature.

It was already discussed in Sec. 2.2.1 that the hydrophobic chain of the surfactant plays an important role for micelle formation: By increasing the chain length, the  $cmc$  decreases. This behavior is depicted in Fig.2.2 which shows the surface tension versus the concentration for a few  $C_iG_1/H_2O$  systems. The  $cmc$  of  $C_8G_1$  is a factor of three smaller than

the *cmc* of  $C_7G_1$ . The determined critical micelle concentrations of  $C_7G_1$  and  $C_8G_1$  are in good agreement with data given in Tab.2.1, while the *cmc* of  $C_8G_2$  is four times lower than comparable data in Tab.2.2. In Appendix E it is suggested that impurities decrease the *cmc*. Detailed information on the surface tension measurements of all investigated sugar surfactants are given in reference [277]. In this work, we use the determined *cmc* values to estimate the concentration range for the thermal diffusion measurements.

## 3.5. Small Angle Neutron Scattering (SANS)

### 3.5.1. Introduction

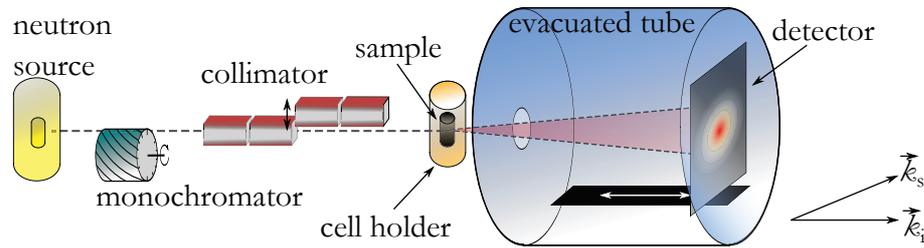

Small angle neutron scattering (SANS) is a method to determine the size and shape of nanostructured matter by analyzing the time averaged intensity distribution of scattered neutrons as function of the scattering vector  $q$ . An advantage of SANS, and hence of neutrons, is the use of uncharged scattered particles. Contrarily to electrons, which are used as scattered particles in small angle x-ray scattering (SAXS) [289–291] or electron diffraction techniques, neutrons are not influenced by the electric field contribution of the scattering particle. Thus, neutrons are able to penetrate deeply into the atomic structure. As neutrons are scattered at the atomic structure and not at the electron cloud in the shell, SANS is sensitive to isotope effects [292]. Due to a nuclear magnetic moment [293], neutrons are greatly used to investigate magnetic materials [294, 295] as neutrons interact with unpaired spins and orbital moments of the particles. The main disadvantage of neutron sources is the low flux density compared to other scattering techniques.

We perform SANS measurements to determine the size and shape of microemulsion droplets at the *efb*. In the following, the SANS technique is briefly introduced.

### 3.5.2. Experimental Setup

We performed SANS experiments using the KWS-1 instrument at FRM2 (Garching, Germany) [296] which is sketched in Fig.3.17. The available neutron flux at the reactor is approximately  $10^{14} \text{ s}^{-1}$  (only thermal neutrons) [297, 298]. At the sample position, the flux is reduced to  $10^6 \text{ s}^{-1}$  to  $10^8 \text{ s}^{-1}$  and depends on the aperture settings and the collimation length. For SANS, thermal neutrons are used with a kinetic energy of less than 100 meV which corresponds to typical wavelengths of 3 – 30 Å. The neutron guide *collects* the reactor neutrons not directly at the source but in a distance of a few centimeters, where the neutrons are slowed down by collisions with the moderator in the reactor containment ( $\text{D}_2\text{O}$ ) to thermal energies at 300 K. The enormous energy distribution of neutrons is pre-selected by a Dornier velocity selector and a chopper. Behind the monochromators, the wavelength distribution is approximately  $\Delta\lambda/\lambda \approx 0.2$  [299]. With the *de Broglie* relation the wavelength,  $\lambda$ , is given by the velocity,  $v$ , and mass of a neutron,  $m$ :

$$\lambda = \frac{h}{mv} \quad (3.23)$$

**Figure 3.17.:** Sketch of the setup for small angle neutron scattering. Neutrons from the reactor are filtered by the monochromator and are focused through the collimator on the sample in the thermostated cell holder. The distribution of scattered neutrons is measured at the detector in an evacuated tube. The detector can be moved to vary the sample-detector distance.

with the Planck constant,  $h$ . For our experiments we used wavelengths of 7 Å and 12 Å.

The neutron beam is focused on the sample position by a collimator. In the KWS-1 instrument, the collimator consists of several apertures with a distance to the sample between 2 m and 20 m. Due to the improved brilliance of the collimated neutron beam, the neutron flux is reduced by several orders of magnitude.

Scattered neutrons are detected on a panel matrix of 128 x 128 channels of  ${}^6\text{Li}$  glass (max pulse rate of 1 MHz and a detection probability of 95 % for 7 Å neutrons) which is mounted on an area of 60 x 60 cm<sup>2</sup>. Unscattered neutrons of the primary beam are blocked. The detector is mounted in the evacuated tube on a slide to tune the distance to the sample between 1.35 m (large scattering angles) and 18 m (small scattering angles).

### 3.5.3. Contrast Factor

Similar to other neutron scattering methods, i.e. neutron reflectivity (NR), SANS takes advantage from different scattering length densities of nuclei of different elements. Hereby, the scattering length density is a measure of the interaction strength of a neutron and a nucleus. Another important advantage of SANS is, that the scattering length density of hydrogen and deuterium have opposite signs [300]. Thus, a variation of scattering length densities can help to achieve a good contrast easily.

The contrast is generally tuned by the exchange of protonated with deuterated solute or solvent molecules [301–304]. The scattering length density of hydrogen is negative, which means that a neutron scattered at a hydrogen nucleus is 180° out of phase relative to those neutrons scattered by the other elements' nuclei. On the other hand, the scattering

length density is positive and in absolute values two times higher for deuterium [291,305]. For the investigation of the shell contrast of the microemulsion droplets, we deuterated the  $n$ -alkane. Therefore, the scattering length density of the alkane is matched to the scattering length density of the surrounding bulk phase by mixing deuterated and protonated alkanes. The determined particle radius by SANS then refers approximately to the point between the surfactant head group and the chain. The *effective* radius of a droplet is obtained by adding 6 Å which is approximately the half length of the surfactant molecule in the interface. The composition of the deuterated mixtures was chosen to achieve the same volume fraction as the protonated mixtures which leads to slightly different mass fractions. The deuteration of the solvent also leads to lower temperatures of the phase boundaries [306,307].

### 3.5.4. Data Analysis

The fundamental variable in SANS measurements is the  $\vec{q}$ -vector, which is defined by the incident wave vector,  $\vec{k}_i$ , and the scattered wave vector,  $\vec{k}_s$ :

$$|\vec{q}| = |\vec{k}_s| - |\vec{k}_i|. \quad (3.24)$$

Its magnitude is given as a function of the scattering angle,  $\theta$ :

$$q = |\vec{q}| = \frac{4\pi n}{\lambda} \sin \frac{\theta}{2} \quad (3.25)$$

with the neutron wavelength,  $\lambda$ , and the refractive index,  $n$ .

In SANS measurements, the scattered intensity distribution is recorded at the detector plane. Edge effects of the detector and distracting pixels are removed with a software and the intensity distribution is radially averaged, denoted as  $I_{\text{sample}}$ .  $I_{\text{sample}}$  needs to be corrected due to the background intensity and contributions from the cell. Then, the measured intensity is calibrated to a standard to obtain the absolute intensity. Plexiglas of 1.5 mm optical path length was used as the calibration standard for which the absolute incoherent scattering intensity is known. It can be used as a reference to determine the detector sensitivity. The absolute intensity of the sample is then calculated by

$$I(q) = \frac{I_{\text{sample}} - I_{\text{bg}} - \frac{T_{\text{sample}}}{T_{\text{ec}}}(I_{\text{ec}} - I_{\text{bg}})}{I_{\text{plexi}} - I_{\text{bg}} - \frac{T_{\text{plexi}}}{T_{\text{ec}}}(I_{\text{ec}} - I_{\text{bg}})} \cdot \frac{T_{\text{plexi}} d_{\text{plexi}}}{T_{\text{sample}} d_{\text{sample}}} \cdot \left. \frac{d\Sigma}{d\Omega} \right|_{\text{plexi}} \quad (3.26)$$

with the transmission of the sample,  $T_{\text{sample}}$ , the background intensity at the detector,  $I_{\text{bg}}$ , the scattered intensity and transmission of the empty cell,  $I_{\text{ec}}$  and  $T_{\text{ec}}$ , respectively, and the intensity and transmission of the calibration standard,  $I_{\text{plexi}}$  and  $T_{\text{plexi}}$ , respectively.  $d$  is the optical length of the cell and  $d\Sigma/d\Omega|_{\text{plexi}}$  is the absolute cross section of the standard.

The absolute intensity as a function of  $q$  (Eq.3.26) is proportional to the form factor,  $P(q)$ , and the structure factor,  $S(q)$ . By the assumption of monodisperse and spherically symmetric particles it can be written as [308]

$$I(q) = N(\Delta\rho)^2 V^2 S(q)P(q), \quad (3.27)$$

with the number density of particles,  $n$ , the difference in the scattering length density between the particles and the solvent,  $\Delta\rho$ , and the volume of the particles,  $V$ . The form factor provides information about the structure of the particles while the structure factor provides information about the particle interaction. In the case of highly diluted systems where particle-particle interactions vanish, the structure factor is equal to one and the absolute intensity only depends on the form factor [309].

Several scattering models have been developed to describe the particle geometries and interaction effects. The form factor for spherical micelles of a homogeneous sphere [310] with an extension for diffuse interface has been proposed by Strey *et al.* [307]. For microemulsion droplets, the scattering contribution of the droplet core was taken into account by Foster *et al.* [311] using a model for a polydisperse spherical Gaussian shells with a diffuse interface [312]. Most simple the structure factor can be analytically derived with the Percus-Yevick approximation [313]. A model for the structure factor was introduced by Baxter [314]. A sticky hard-sphere potential is assumed which describes the particles as hard spheres with an attractive delta function potential at the surface. An overview about the various mathematical expressions regarding the form factor and the structure factor which are used in this work can be found in the thesis of Sascha Datta [277].

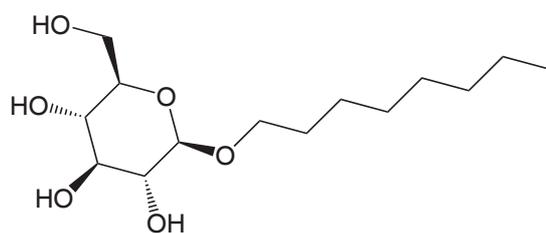

## SORET EFFECT OF $C_8G_1$ IN WATER AROUND THE *CMC*

We studied the thermal diffusion behavior of the nonionic surfactant  $C_8G_1$  (*n*-Octyl  $\beta$ -D-glucopyranoside) in water for different concentrations between  $w=0.25$  wt% and 2.0 wt% in a temperature range from 15 °C to 60 °C using the classical and infrared thermal diffusion forced Rayleigh scattering (TDFRS) setup.

The purpose of this chapter is the investigation of the thermal diffusion behavior of surfactant systems around the critical micelle concentration (*cmc*), which is independently determined by surface tension measurements.

### 4.1. Introduction

Several experimental techniques have been used to study the thermal diffusion behavior of surfactant systems. Piazza *et al.* investigated an ionic surfactant, sodium dodecyl sulphate (SDS), in water using a beam deflection and a thermal lens setup [37,48]. They found that  $S_T$  increases with increasing salt concentration due to the strong influence of intermicellar interactions. They investigated also the nonionic surfactant  $\beta$ -dodecyl maltoside ( $C_{12}G_2$ ), which has the same hydrophobic tail as SDS and two glucose rings as head group.  $C_{12}G_2$ -micelles showed a strong tendency to move to the cold region ( $S_T > 0$ ), which might be caused by the interaction of the surface of micelles with the solvent via hydrogen bonds. Ning *et al.* studied a series of nonionic surfactants in water

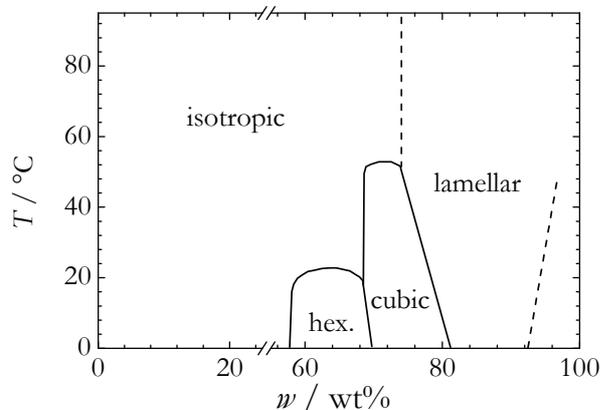

**Figure 4.1.:** Molecular structure of  $\beta$ - $C_8G_1$ .

in a wide temperature and concentration range using the thermal diffusion forced Rayleigh scattering (TDFRS) technique [39,40]. For their measurements a small amount of an ionic dye (Basantol<sup>®</sup> Yellow) is added in order to create a sufficient temperature gradient. The measurements show that the addition of the dye influences the thermal diffusion behavior considerably. Therefore the IR-TDFRS setup has been developed to avoid the addition of dye for aqueous systems [75].

Santos *et al.* investigated the Soret coefficient of potassium laurate in water and found an abrupt change of the matter lens signal at the  $cmc$  [34]. Unfortunately, an evaluation of  $S_T$  was not possible due to the presence of the dye which complicated the analysis. Therefore, it remained unclear to which extent the  $cmc$  is also visible in the thermal diffusion, diffusion and Soret coefficient. To clarify these observations the thermal diffusion behavior of micellar systems with a high  $cmc$  needs to be investigated without the addition of dye.

Among the wide range of surfactants we found nonionic sugar surfactants with a fairly high  $cmc$ , such as *n*-Octyl  $\beta$ -D-glucopyranoside, in the following referred to as  $C_8G_1$  [315]. The  $\beta$ -form has a linear molecular structure which is shown in Fig.4.1. Additionally, an  $\alpha$ -L-form exists, which differs in the linkage between the hydrophilic head and the hydrophobic chain of the alkyl glucoside [207,316], but this less common  $\alpha$ -form will not be considered here.

Many properties such as the phase and structural behavior, the influence of salt, but also the solute-solvent interactions have been studied for aqueous solutions of  $C_8G_1$  [207,223,317]. From previous studies on aqueous systems [62,140] we know that the solute-solvent interaction and the capability to form hydrogen bonds often influence the thermal diffusion behavior. Pastor *et al.* [317] determined the number of water molecules (*hydration number*), surrounding the  $C_8G_1$  molecules. They found a hydration number of 16 for monomers below the  $cmc$ , which is decaying exponentially above the  $cmc$  to 8 for concentrations around 1.5 wt%, while at the same time the aggregation number increases

**Figure 4.2.:** Phase diagram of  $C_8G_1$ , redrawn from Nilsson *et al.* [207].

from  $54 \pm 5$  to  $104 \pm 5$  when increasing the concentration from 0.85 to 1.5 wt%. They also observed a slight shift of the *cmc* to lower concentrations when adding salt.

In the following, we determine the *cmc* of  $C_8G_1$  in water in a temperature range between 15 °C and 40 °C by surface tension measurements and study the thermal diffusion behavior of the system using both, the classical TDFRS as well as the IR-TDFRS. The classical TDFRS has been used to study the system in the presence of dye as it was also done in the work by Santos *et al.* [34]. Therefore, we had also to investigate to which extend the *cmc* is shifted in the presence of the trivalent dye Basantol<sup>®</sup> Yellow. In order to gain a better understanding of the influence of the dye on the transport properties we performed experiments with the IR-TDFRS without and also in the presence of dye.

## 4.2. Experiment and Data Analysis

### 4.2.1. Sample Preparation and Characterization

*n*-Octyl  $\beta$ -D-glucopyranoside was purchased from Glycon Biochemicals (Germany) with a purity of 99.5 %. The molecular structure is depicted in Fig.4.1. A phase diagram of the aqueous surfactant system  $C_8G_1/H_2O$  (without dye) was recorded by Nilsson *et al.* [207] and is shown in Fig.4.2.

All samples were prepared by weighting with the accuracy of the balance ( $\pm 0.0001$  g). Deionized Milli-Q water was used as solvent. In the classical TDFRS setup we used

for all measurements a tiny amount of  $1.5 \times 10^{-4}$  M of the ionic dye Basantol<sup>®</sup> Yellow (BASF) [40]. The optical density was adjusted to  $2 \text{ cm}^{-1}$  at a wavelength of  $\lambda = 488 \text{ nm}$  using a Carry 50 spectrometer. For the absorption measurements we use cells with a thickness of 1 mm. For the IR-TDFRS and classical TDFRS measurements, the surfactant solutions were directly filtered into the sample cell by a PTFE (Roth) filter with a mesh size of  $5 \mu\text{m}$ . The Hellma flow cells, used for both TDFRS experiments, have an optical thickness of 0.2 mm.

For all experiments, the sample cell in the TDFRS setups was thermostated in a brass or copper holder for at least half an hour. The selected material of the sample holder has a high thermal conductivity and thus allows a fast equilibration and homogeneous profile of the temperature in the sample holder. The temperature of the holder was controlled by a circulating water bath (Lauda E300 thermostat) with a stability of  $\pm 0.02 \text{ K}$ . The classical TDFRS and IR-TDFRS measurements were performed in a concentration range between 0.25–2.0 wt% and in a temperature between  $15 \text{ }^\circ\text{C}$  and  $40 \text{ }^\circ\text{C}$ , and for chosen samples in a temperature range up to  $60 \text{ }^\circ\text{C}$ .

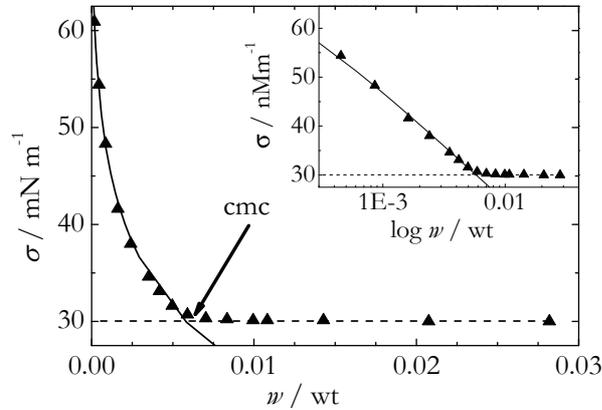

#### 4.2.2. Determination of the Critical Micelle Concentration

The critical micelle concentration was determined by surface tension measurements, which were performed with a Krüss digital tensiometer K10T. Concentration series of the  $C_8G_1$ /water mixture at  $15 \text{ }^\circ\text{C}$ ,  $20 \text{ }^\circ\text{C}$ ,  $30 \text{ }^\circ\text{C}$  and  $40 \text{ }^\circ\text{C}$  were measured. The dye-containing mixtures were studied at  $23 \text{ }^\circ\text{C}$  and  $30 \text{ }^\circ\text{C}$ , respectively. The temperature was controlled with an accuracy of  $\pm 0.1 \text{ K}$ .

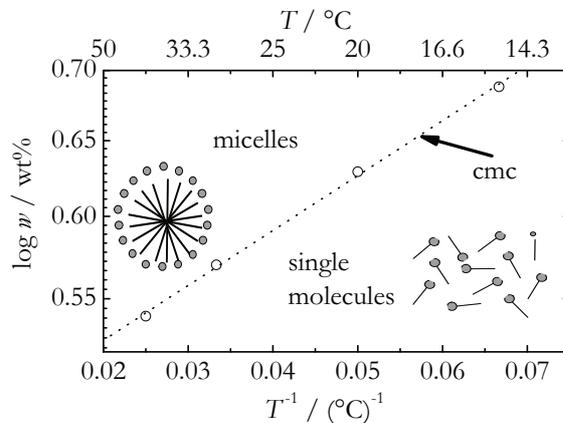

The trend of the surface tension versus the logarithm of the concentration was analyzed using the Langmuir-Szyszkowski-equation [288] in eq. 3.22 below the *cmc* (see Fig.4.3). Above the *cmc*, the surface tension is almost constant, thus this range was fitted linearly. The intersection of both curves marks the *cmc*. Detailed information on the measuring method are given in section 3.4.

#### 4.2.3. Influence of the Dye on the *cmc*

The classical TDFRS setup suffers from the addition of dye to convert the intensity grating of the Ar-laser into a thermal grating. Especially for aqueous mixtures, it has turned out that it is difficult to find an inert dye, which does not influence the experiment.

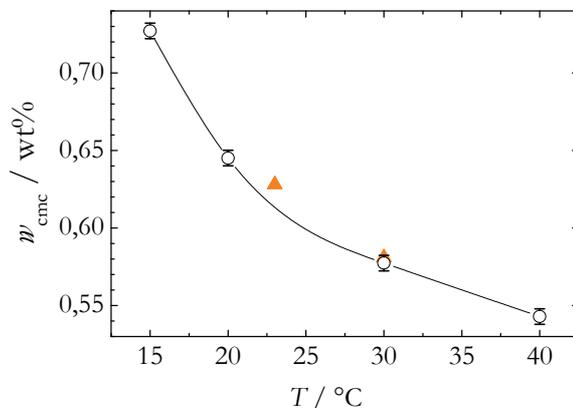

**Figure 4.3.:** The surface tension as function of the concentration of the binary system  $C_8G_1/H_2O$  at  $30\text{ }^\circ\text{C}$ . The continuous line marks the fit with the Langmuir-Szyszkowski equation (see Eq. 3.22) at low concentrations, the linear fit (dashed line) was obtained from fitting for the seven highest measured concentrations. The intersection point marks the cmc. Inset: The same data plotted in a logarithmic scale of the concentration.

**Figure 4.4.:** Temperature dependence of the cmc for the  $C_8G_1/H_2O$  system. The cmc scales linearly with the inverse temperature.

Water soluble dyes often change their absorption behavior with  $pH$  or temperature [318, 319]. In complex systems the addition of dye can also influence the phase behavior and microstructure of the micellar system and also its thermal diffusion behavior [38].

To investigate the influence of the ionic dye on the  $cmc$  we performed measurements with the same dye concentrations (full circles and full rectangles in 4.6), corresponding

**Figure 4.5.:** The critical micelle concentrations at several temperatures for the  $C_8G_1/H_2O$  system. The cmc of the dye-infected system (triangles up) is compared with the dye-free surfactant system (circles). The effect of the dye on the cmc is negligible.

to the dye-concentration in the TDFRS experiments. Two critical micelle concentrations of  $C_8G_1/H_2O$  with dye at 23 °C and 30 °C were determined and compared with dye-free mixtures. The results are shown in Fig.4.5. At this rather low concentration we did not see a significant influence of the dye and the dye infected mixture showed nearly the same cmc values as the surfactant mixture which was measured in the absence of dye. Deviations only occurred in the order of the error bars. Pastor *et al.* found a change of the cmc of  $C_8G_1$  in water of 10-15 % adding 0.05 M  $CaCl_2$  or  $ZnCl_2$  [317]. Since the dye concentration in our experiments was about two orders of magnitude smaller we would expect only a change of the cmc in the sub-percent range, which is in agreement with our results.

#### 4.2.4. Data Analysis

The normalized diffraction signal,  $\zeta_{\text{het}}$ , is described and analyzed by Eq.3.8. The increment of the refractive index with concentration,  $(\partial n / \partial w)_{p,T}$ , at constant pressure and temperature was measured with a refractometer (Anton Paar). Five measurements were performed for each concentration to reduce the error.

For the determination of  $(\partial n / \partial T)_{p,w}$  at constant pressure and surfactant concentration an Michelson interferometer was used. In general, the  $(\partial n / \partial T)_{p,w}$  measurements of  $C_8G_1$  so-

lutions as function of the surfactant weight fraction were done between 15 °C and 40 °C. For a few weight fractions we performed measurements up to 60 °C.

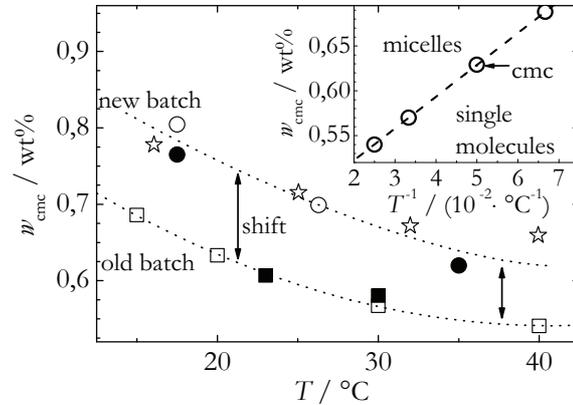

According to Rosen [320] and Preston [321] it should also be possible to determine the critical micelle concentration from the variation of the refractive index with concentration. However, by measuring the refractive index as function of concentration we found an almost perfect linear concentration dependence, which makes it impossible to determine the *cmc*. To our knowledge, the refractive index measurements are not favored for the *cmc* determination of C<sub>8</sub>G<sub>1</sub> in H<sub>2</sub>O. Instead, Strop and Brunger [322] used refractive index measurements for the determination of the surfactant concentration in solution for aqueous systems with low *cmc* values, namely nonaethylene glycol monododecyl ether (C<sub>12</sub>E<sub>9</sub>, *cmc* = 100 μM [323]) and *n*-dodecyl-β-D-maltopyranoside (C<sub>12</sub>G<sub>2</sub>, *cmc* = 230 μM [324]). They found a linear relationship between the change of the refractive index and the surfactant concentration in the investigated low concentration range. They expect that this relationship can be used for methods to determine the surfactant concentration by measuring the refractive index also for high *cmc* systems, if lower-sensitivity detectors are used.

## 4.3. Results and Discussion

### 4.3.1. Surface Tension Measurements

As already described we determined the critical micelle concentration by surface tension measurements. The temperature dependence of the *cmc* is shown in Fig.4.6. We studied two different batches of C<sub>8</sub>G<sub>1</sub>: an old batch (rectangles) (Glycon, 2005) and a new one (circles) (Glycon, 2008). We found systematically larger *cmc* values for the new batch, however this difference could be explained with a changed workup method in the production process (notice by manufacturer). Anyway, the temperature dependence of the *cmc* is qualitatively the same for both batches. To avoid misunderstanding, we performed all TDFRS measurements with the new C<sub>8</sub>G<sub>1</sub> batch.

The *cmc* was determined at several temperatures in a range from 15 °C to 40 °C. The *cmc* decreases with increasing temperature and describes a parabolic shape in a temperature dependence (not shown in Fig.4.5). The polynomial 2<sup>nd</sup> order fit of this curve shows a minimum point at 42 °C. This is a typical behavior of nonionic systems as the hydrogen bonds break at higher temperatures which is discussed in Sec.2.2.1. It is shown in Fig.4.4,

**Figure 4.6.:** The  $cmc$  for  $C_8G_1/H_2O$  was determined by surface tension measurements without ( $\circ$ ,  $\square$ ) and with dye ( $\bullet$ ,  $\blacksquare$ ) for the old ( $\square$ ,  $\blacksquare$ ) and the new surfactant batch ( $\circ$ ,  $\bullet$ ), and compared with literature values by Aoudia and Zana [220] ( $\star$ ). The error bars are in the order of the symbol size. Inset: The  $cmc$  as function of the inverse temperature in Celsius. The dashed line is a linear fit to the data points.

that plotting the logarithmic  $cmc$  versus the inverse temperature gives a linear dependence (dotted line). Below this line the surfactant monomers are dissolved in water, while above a dynamic equilibrium of monomers and micelles exists.

For both batches we observed a decay of the  $cmc$  with increasing temperature. This can be explained with a decreasing hydrophilicity of the surfactant molecules with increasing temperature due to the decreasing ability to form hydrogen bonds. Typically the  $cmc$  of nonionic surfactants passes through a minimum and increases at higher temperatures again [220,221]. In the investigated temperature range up to 40 °C we did not observe the minimum and the final increase, but Aoudia and Zana [220] observed a shallow minimum around 42 °C for the same surfactant system. A polynomial 2<sup>nd</sup> order fit of our data (dashed line in 4.6) shows, that we can expect a similar minimum temperature at 42 °C for the minimum  $cmc$ . The position of the minimum is determined by the size of the head group, which is fairly large in the case of the sugar surfactant. Also for different polyoxyethylene glycol monododecyl ethers  $C_{12}E_j$  with oxyethylene chain units of  $j = 4, 6$  and  $8$  a shift of the minimum from 40 °C to 50 °C has been observed [221].

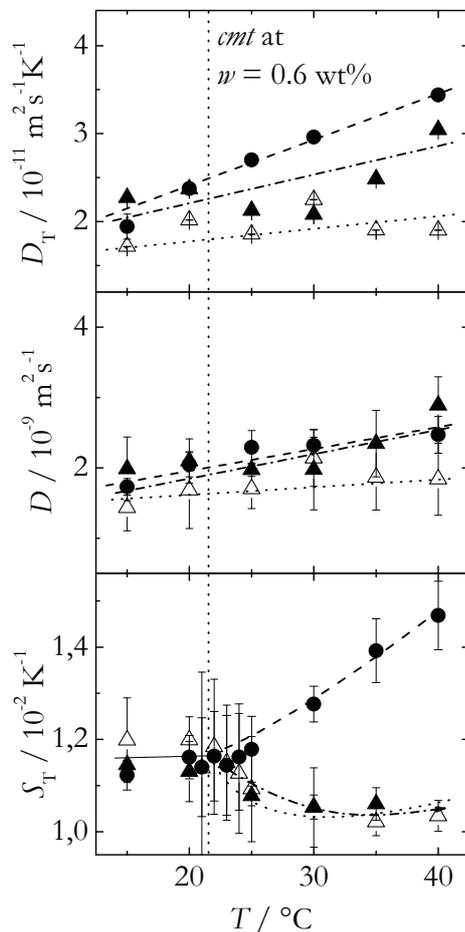

### 4.3.2. Thermal Diffusion Behavior around the *cmc*

Below the *cmc*, the surfactant molecules in solution are in equilibrium with those adsorbed at the water-air interface. Above the *cmc* also micelles are formed in the solution. Therefore, we will observe the thermal diffusion behavior of the individual surfactant molecules below the *cmc*, while above the *cmc* we have additionally a thermophoretic motion of the micelles. This might also lead to a pronounced change of the thermal diffusion or Soret coefficient.

For the surfactant system under study the determined Soret coefficients correspond to an averaged value. We can not differentiate between the contribution stemming from the  $C_8G_1$  molecules and micelles, as it can be done for a polymer in a solvent mixture [62]. In the latter case the diffusion process of the solvent mixture and the polymer can be differentiated, because the time constants of the two processes differ by more than one order of magnitude. For the micellar solution the time constants of the single molecules and the micelles are so close that we can not separate the two processes in the experimental signal. Therefore, we observed only an averaged value, which describes the thermal diffusion motion of  $C_8G_1$  in water. Depending on the location in the phase diagram the signal can be a superposition of different contributions. A detailed analysis of the different contributions in a phenomenological approach suggested by Santos *et al.* is not possible [34].

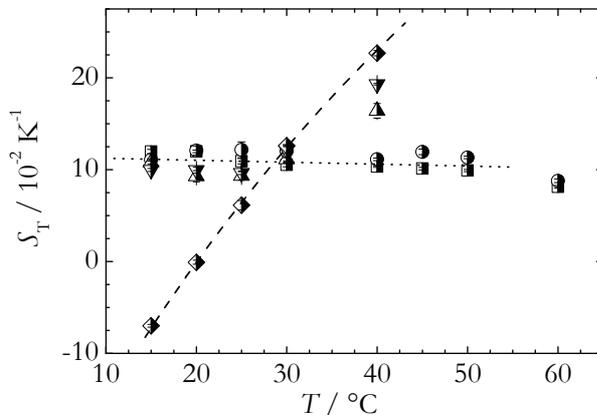

In the following we compare the results of both TDFRS setups in order to determine the influence of the dye. In Fig.4.7 we show the temperature dependence of the Soret coefficient, the thermal diffusion coefficient and diffusion coefficient for a sample with a surfactant concentration of  $w=0.6$  wt% where we found the *cmc* at 23 °C. In the plot we display data obtained by IR-TDFRS and classical TDFRS. In the latter case the samples contained Basantol<sup>®</sup> Yellow as dye. Additionally, we performed measurements with the IR-TDFRS in the presence of dye.

The diffusion coefficient,  $D$ , and the thermal diffusion coefficient,  $D_T$ , increased continuously with temperature. None of the diffusion coefficients showed a noticeable change at the *cmc*. The difference of  $D$  obtained with the different setups is almost negligible although  $D$  obtained with the classical setup was systematically larger, which might indicate smaller micelles or attractive interactions. In our case the addition of the dye led to charged micelles, which repelled each other and which should have led to slower dynamics [325,326]. Surprisingly, in our case the diffusion became faster, when the micelles were charged (middle chart in Fig.4.7). This might be explained by an inhomogeneous heating of the dye-containing micelles, which leads to a faster movement.

**Figure 4.7.:** Comparison of  $S_T$ ,  $D_T$  and  $D$  as function of the temperature for  $w=0.6$  wt% in IR-TDFRS ( $\triangle$  (without dye),  $\blacktriangle$  (with dye)) and classical TDFRS ( $\bullet$ ). Bottom: Above the cmt we observe larger  $S_T$ -values in classical TDFRS than in IR-TDFRS. Independent of the method or the presence of the dye we find the same Soret coefficients below the cmt at 23 °C within the error bars of approximately 10 %.

The temperature dependent slope of  $D_T$  measured with the classical TDFRS is larger than the one measured without dye in the IR-TDFRS. We assume that the dye was incorporated into the micelles and the interfacial energy of the micelles changes. This assumption is supported by the fact that the molar fraction of the dye molecules and micelles is in the same order of  $1.5 \times 10^{-4}$  mol/l, if we take into account the aggregation numbers determined by Pastor *et al.* [317]. The incorporation of the dye into the micelles influences also the diffusion coefficient. The reason could be either that the interaction

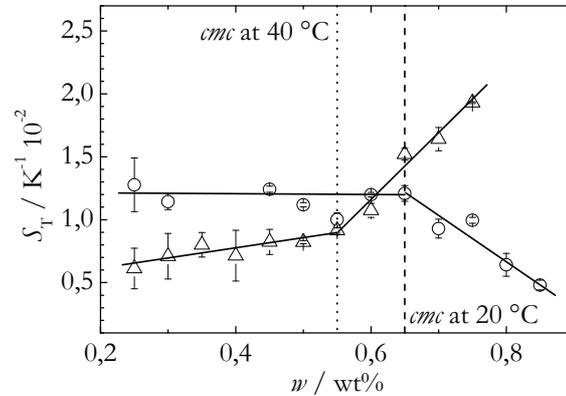

**Figure 4.8.:** The Soret coefficient  $S_T$  as function of temperature determined with the IR-TDFRS without dye. Concentrations: 0.6 wt% (squares), 0.65 wt% (circles), 0.7 wt% (triangles up), 0.75 wt% (triangles down) and 1.0 wt% (diamonds).

energy changes due to a modified interfacial energy or that the shape is modified. The latter we will have to confirm by neutron scattering experiments.

Below the *cmc* all Soret coefficients agree within their error bars and  $S_T$  is temperature independent (cf. Fig.4.7). For temperatures above the *cmc* we observed, that the Soret coefficient for the classical setup was larger compared to the IR setup. In the classical TDFRS the incorporation of the dye in the micelles probably induced a stronger local heating, which modified the thermal diffusion behavior strongly. This was probably also the reason leading to the abrupt change of the thermal lens signal of the aqueous potassium laurate solution with Congo red [34]. We suspect that it is really necessary to create the thermal grating with the absorbing wavelength, because recent experiments on a nonionic surfactant with Basantol<sup>®</sup> Yellow as dye [38] showed that homogeneous illumination with a blue laser in the IR-TDFRS does not have the same effect.

In Fig.4.8 the temperature dependence of the Soret coefficient is plotted for different concentrations above and below the *cmc*. Those concentrations above 0.65 wt% indicated an increase of  $S_T$  with temperature, others below 0.65 wt% not. As we already found, the Soret coefficient is independent from temperature in the molecular regime and only the contribution of micelles cause a change of  $S_T$ . Thus, it is expected that the *cmc* is determined in this plot approximately at 0.65 wt%.

We were also able to determine the *cmc* by plotting the Soret coefficient as a function of the sugar surfactant concentration as shown in Fig.4.9. For both temperatures the slope

**Figure 4.9.:** The Soret coefficient versus the surfactant concentration at constant temperatures of 20 °C (○) and 40 °C (△) using IR-TDFRS without dye. The vertical lines mark the *cmc* at 20 °C (dashed) and 40 °C (dotted). The solid lines are guides to the eye.

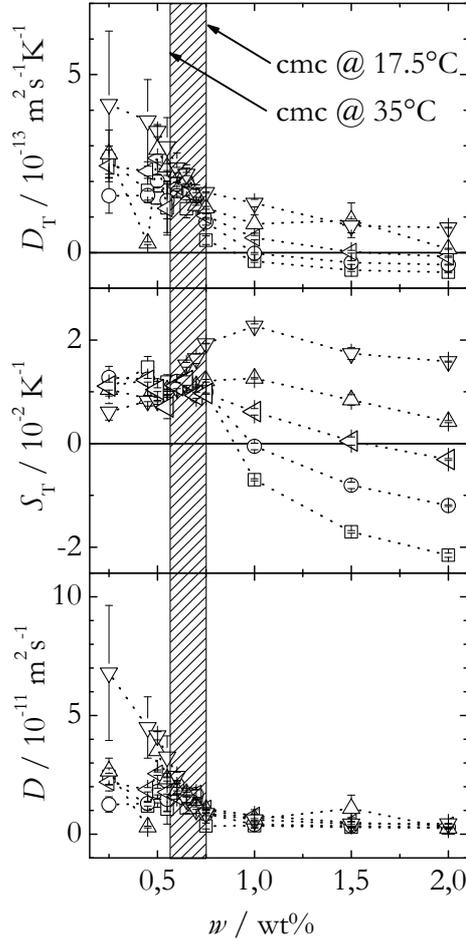

of the Soret coefficient changed clearly at the *cmc*. While the slope at 20 °C changed from zero to negative, the positive slope at 40 °C (dotted vertical line) became more pronounced above the *cmc*. For both temperatures below the *cmc* the concentration dependence of  $S_T$  was less pronounced. The measurements with the classical TDFRS setup did not give a better indication of the *cmc*. For clarity the data are not displayed. The obtained *cmc* values are in good agreement with the results from the surface tension measurements.

### 4.3.3. Results for higher concentrated Solutions

We also investigated the thermal diffusion behavior for higher surfactant concentrations. Fig.4.10 shows the thermal diffusion  $D_T$ , the diffusion  $D$  and the Soret coefficient  $S_T$  as function of concentration at different temperatures.

For all temperatures the thermal diffusion coefficient decreased with increasing surfactant concentration and with decreasing temperature (cf. top of Fig.4.10). For the three lower temperatures of  $T = 15$  °C, 20 °C and 25 °C a sign change occurred at a concentration of 0.9 wt%, 1.0 wt% and 1.6 wt%, while  $D_T$  stayed positive at higher temperatures. The decay of  $D_T$  became weaker for higher concentrations. As can be seen in the middle part of Fig.4.10 the diffusion coefficient  $D$  decreased for lower concentrations, while above the *cmc* the diffusion was almost independent of the concentration.

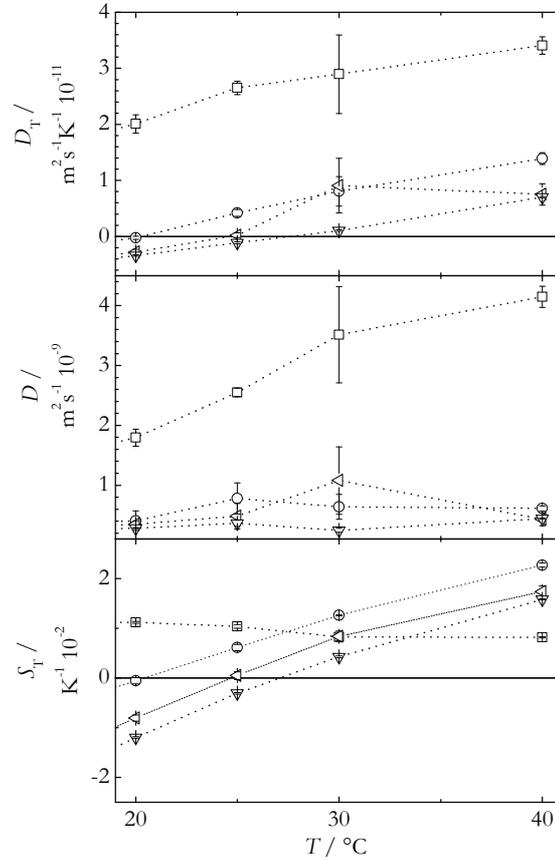

In the bottom part of Fig.4.10 the concentration dependence of the Soret coefficient is

**Figure 4.10.:** The thermal diffusion  $D_T$ , the diffusion  $D$  and the Soret coefficient  $S_T$  versus the concentration at different temperatures: 15 °C ( $\square$ ), 20 °C ( $\circ$ ), 25 °C ( $\triangleleft$ ), 30 °C ( $\triangle$ ), 40 °C ( $\nabla$ ).

shown for different temperatures.  $S_T$  passed through a maximum for  $T = 20$  °C and 40 °C before it was decaying almost linearly above a concentration of 1.0 wt%. By decreasing the temperature this decay became steeper. For the two highest temperatures at 30 °C and 40 °C we did not observe a sign change in the investigated concentration range, but it is expected that it will occur at higher concentrations.

The decay of the Soret coefficient at high concentrations seems to be a typical phenomena and has also been found for polymer solutions [327] and colloidal dispersions [42]. In the semidilute concentration range the Soret coefficient of the polymeric system showed an asymptotic scaling law with concentration  $S_T = C_0 \cdot C^{-0.65}$ , whereas the exponent changed

**Figure 4.11.:**  $D_T$ ,  $D$  and  $S_T$  versus temperature in the IR-TDFRS. Concentrations: 0.5 wt% ( $\square$ ), 1.0 wt% ( $\circ$ ), 1.5 wt% ( $\triangleleft$ ) and 2.0 wt% ( $\nabla$ ).

from -0.65 to -1 approaching the concentrated regime. For the colloidal system an asymptotic power law for the Soret coefficient in dependence of the volume fraction  $\phi$  of the form  $S_T = \phi_0 \cdot \phi^{-0.0095}$  has been found. For the investigated sugar surfactant system the exponent is not temperature independent but decreases from -0.42 to -1.44 with decreasing temperature.

Fig.4.11 shows the temperature dependence of  $D_T$ ,  $D$  and  $S_T$  up to a concentration of 2.0 wt%. The temperature dependence of  $S_T$  was negligible small for concentrations below the *cmc*, for instance 0.5 wt%, and became more pronounced for higher concentrations (2.0 wt%). For sufficiently high concentrations we observed a sign change of  $S_T$  from negative to positive with increasing temperature. The sign change temperature as well as the slope of the temperature dependence of  $S_T$  increased with increasing concentration.

The sign change from negative to positive  $S_T$ -values is a typical behavior of aqueous polymer and colloidal systems [48,328]. Sugaya *et al.* [328] found for aqueous dextran solutions that the temperature dependence was concentration independent. They were able to shift the sign change temperature towards lower temperatures by adding urea, which functioned as a hydrogen bond breaker so the system becomes more "thermophobic" and dextran moves to the cold side. We observe the same trend with increasing temperature when the hydrogen bond formation is weakened. An increase of the sugar surfactant concentration leads to more surface groups interacting via hydrogen bonds and results in a more "thermophilic behavior".

## 4.4. Conclusion

We measured the diffusion coefficients and the Soret coefficient of the nonionic sugar surfactant  $C_8G_1$  for different concentrations and temperatures. Special attention has been paid to the region around the critical micelle concentration, which has been determined independently by surface tension measurements.

As expected we find a slower diffusion for the micelles compared to the single sugar surfactant molecules. Although the surface tension measurements indicate that the *cmc* is not influenced by the presence of the dye, we find a pronounced influence of the dye in the thermal diffusion measurements. Below the *cmc* the results for all methods give identical results indicating that the dye diffuses as the sugar surfactant molecules freely in the water. Above the *cmc* we find a much larger value of the Soret coefficient with the classical TDFRS setup compared to the IR-TDFRS. This effect might be explained by local heating of the dye infected micelles. A similar mechanism might also have led to an abrupt change of the matter lens signal in the work by Santos *et al.* [34]. Nevertheless, we find also a change in the slope of the concentration dependence of the Soret coefficient determined with the IR-TDFRS without the dye below and above the critical micelle concentration (cf. Fig.4.9). One hypothesis in understanding the change of the thermodiffusion behavior near the *cmc* is that the thermal diffusion motion arises from unbalanced stresses localized in a thin layer close to the molecule-particle surface, which is primarily determined by the nature and strength of particle-solvent interactions. Following this concept, it seems to be natural to expect a change in the Soret coefficient once micelles are formed, because part of the surfactant molecules are hidden in the inside of the micelles, so that the direct interaction with the solvent is screened.

At higher surfactant concentrations above 1.0 wt% a sign change has been observed. With increasing temperatures the sign change shifts towards higher concentrations and with increasing concentration the sign change occurs at higher temperatures. The behavior is in analogy with results for concentrated polymeric and colloidal systems and part of the behavior can be explained by the balance of the hydrogen bond formation. We expect that a similar behavior can also be observed for other surfactant systems.

INVESTIGATION OF SUGAR SURFACTANT MICELLES  
USING IR-TDFRS

In chapter 4 aqueous *n*-Octyl  $\beta$ -D-glucopyranoside solutions were used as a model system to investigate the thermal diffusion behavior in the vicinity of the critical micelle concentration. It was shown that the *cmc* is detectable in TDFRS measurements. Additionally, a sign inversion of the Soret coefficient was observed at higher concentrations.

In this chapter, we describe the same measurements in the concentration regime close to the *cmc* for other sugar surfactants to investigate, if the previous findings are general features of this surfactant class. We also wanted to investigate how structural changes such as the number of head groups or the length of the alkyl chain influence the thermal diffusion properties. Therefore, we selected *n*-Heptyl  $\beta$ -D-glucopyranoside (**C<sub>7</sub>G<sub>1</sub>**) and *n*-Octyl  $\beta$ -D-maltopyranoside (**C<sub>8</sub>G<sub>2</sub>**). As it was introduced in Sec.2.2.1, the *cmc* of **C<sub>8</sub>G<sub>1</sub>** and **C<sub>8</sub>G<sub>2</sub>** is almost equal but the two head group units of the maltoside (see Fig.5.1-c) cause changes in the micellar shape. In contrast, the shorter carbon chain of **C<sub>7</sub>G<sub>1</sub>** (Fig.5.1-a) decreases the hydrophobicity and thus raises the *cmc*. The *cmc* of **C<sub>7</sub>G<sub>1</sub>** and **C<sub>8</sub>G<sub>2</sub>** was precisely determined by surface tension measurements for several temperatures. Although a few literature values of the *cmc* are available (see Tabs.2.1 and 2.2), the temperature dependence of the *cmc* is rarely investigated. A second point was the investigation of the  $S_T$  sign inversion at higher surfactant concentrations. It was suggested that the sign inversion could be related with the *cmc*, as both effects originate from changes in the solute-solvent interactions. In the last part of this chapter, the obtained

data were correlated with literature results, i.e. the hydration number or the second virial coefficient.

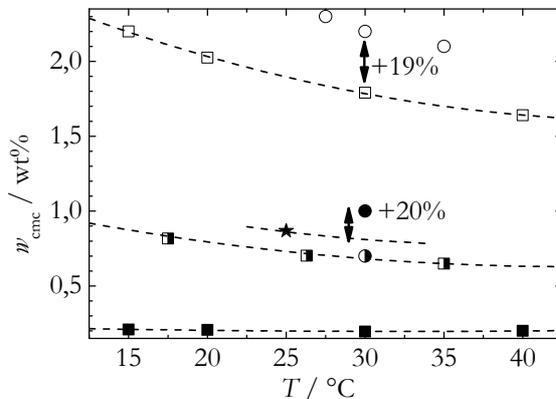

## 5.1. Sample Preparation and Characterization

The sugar surfactants were bought from Glycon (Germany) and a second batch of C<sub>8</sub>G<sub>2</sub> was purchased from Sigma-Aldrich (Germany). All products were used without further purification. It is emphasized that each order of surfactants contains only surfactants from one batch. This is pointed out because the *cmc* of different batches for C<sub>8</sub>G<sub>1</sub> (see Fig.4.5) differ because Glycon had modified the synthesis.

Tab.5.1 lists the chemical properties of all investigated surfactants. Millipore water was used as solvent. Hellma flow cells with an optical path length of 0.2 mm were used for the measurements in the IR-TDFRS setup. The aqueous surfactant solutions were directly filtered into the sample cell through a PTFE-filter (Roth) with a pore size of 0.2 μm which was two orders of magnitude larger than the estimated size of micelles. The refractive index increments with temperature were determined in a temperature range from 12 °C to 63 °C using Hellma absorption cells with an optical path length of 10 mm.

**Figure 5.1.:** Molecular structure of the alkyl-polyglucosides under investigation with the sketched hydrogen (white), carbon (grey) and oxygen atoms (red).

**Figure 5.2.:** The cmc for  $\text{C}_i\text{G}_j/\text{H}_2\text{O}$  versus temperature. The cmc was determined by surface tension measurements (squares) for  $\text{C}_7\text{G}_1$  (open squares),  $\text{C}_8\text{G}_1$  (half-filled squares) and  $\text{C}_8\text{G}_2$  (filled squares). The circles indicate the cmc found by IR-TDFRS. The star is a literature value [239]. Dashed lines are quadratic fits.

## 5.2. Determination of the cmc

The critical micelle concentration was determined by the group in Köln performing surface tension measurements using the ring-method in a temperature range from 15 °C to 40 °C for  $\text{C}_7\text{G}_1$  and  $\text{C}_8\text{G}_2$ , and from 17.5 °C to 35 °C for  $\text{C}_8\text{G}_1$ . Fig.5.2 summarizes the cmc values. For all surfactants, a continuous decrease of the cmc with increasing temperature was observed and a quadratic dependence could be assumed which is typical for nonionic surfactants (see Sec.2.2.1). The highest cmc was determined for  $\text{C}_7\text{G}_1$  (0.02025 wt at 20 °C), followed by  $\text{C}_8\text{G}_1$  (0.00643 wt at 20 °C) and  $\text{C}_8\text{G}_2$  had the lowest cmc (0.00207 wt at 20 °C). The cmc values of  $\text{C}_7\text{G}_1$  and  $\text{C}_8\text{G}_1$  were comparable to literature values which are listed in Tab.2.1. In contrast, the determined cmc of  $\text{C}_8\text{G}_2$  was by a factor of four lower than expected. We repeated the determination of the cmc for another batch from another manufacturer but found a similar low value. With HPLC-MS we detected some impurities in  $\text{C}_8\text{G}_2$ , which were probably enriched in the interface and led to the much too low cmc. A detailed discussion can be found in Appendix E. More details of the surface tension measurements were given by Datta [277]. In this work, the cmc values were only used as references to choose the concentration range which had to be investigated in thermal diffusion measurements.

We also calculated the area per surfactant head group in the micelle-solvent interface,

$A_{\min}$ , to check whether the number of head group units of the surfactant takes influence on that property. Therefore, we used Eq.5.1 to calculate the maximum surface excess concentration,  $\Gamma_{\max}$ , at the air-solvent interface

$$\Gamma_{\max} = \frac{1}{2.303nRT} \left( \frac{\partial \gamma}{\partial \log w_{\text{cmc}}} \right)_T \quad (5.1)$$

with the particle density,  $n$ , the universal gas constant,  $R$ , and  $(\partial \gamma / \partial \log w_{\text{cmc}})_T$  is the slope of the surface tension with concentration at constant temperature below the *cmc*. Then,  $A_{\min}$  is derived by

$$A_{\min} = (\Gamma_{\max} N_A)^{-1} \quad (5.2)$$

with the Avogadro constant,  $N_A$ . We found that  $A_{\min}$  increases linearly with increasing temperature. It was indicated that the area per surfactant head group was almost independent from the alkyl chain length for the different glucoside surfactants with slightly larger values for  $C_7G_1$ .  $A_{\min}$  of the glucoside micelles is in the range between 0.44 nm<sup>2</sup> (15 °C) and 0.48 nm<sup>2</sup> (40 °C). However, we measured much lower values for the maltoside surfactant in the range of 0.35 nm<sup>2</sup> (15 °C) to 0.40 nm<sup>2</sup> (40 °C). The results of the latter surfactant system agree with measurements by Boyd *et al.* [239] who determined an area of 0.42 nm<sup>2</sup> at 25 °C.

Assuming spherical micelles at the *cmc* for all surfactants, we used the determined hydrodynamic radii from IR-TDFRS measurements (they are discussed later) and calculated an aggregation number per micelle of 45 for  $C_7G_1$  ( $w = 0.023$  wt, 40 °C), 71 for  $C_8G_1$  ( $w = 0.0075$  wt, 40 °C) and 27 for  $C_8G_2$  ( $w = 0.01$  wt, 40 °C). The value for  $C_8G_1$  agreed with literature results [211,226,329], those of  $C_8G_2$  agreed with results by Boyd *et al.* [239] and He *et al.* [215].

### 5.2.1. The Soret Coefficient of $C_7G_1/H_2O$ Mixtures

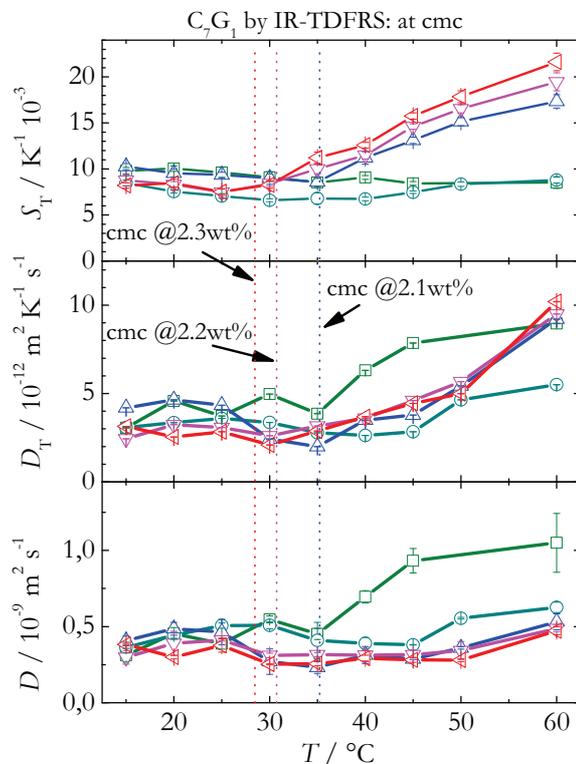

All thermal diffusion measurements of the aqueous surfactant solutions were performed in the vicinity of the *cmc* using the IR-TDFRS setup in a temperature range from 15 °C to 60 °C. The concentration range was chosen that it covered the *cmc*, and at least two concentrations above and below in an approximate range between  $0.5 \cdot \text{cmc}$  and  $1.5 \cdot \text{cmc}$  were measured.

In Fig.5.3 the temperature dependence of the Soret and diffusion coefficients is shown. In the lower temperature regime the Soret coefficient is below 0.01 K<sup>-1</sup> and almost the

same for all concentrations within the error bars. A similar behavior was observed for the mass and thermal diffusion coefficient. This indicated that only the surfactant molecules contributed to the thermal diffusion behavior, and all investigated concentrations were below the *cmc* in this temperature regime. At higher temperatures,  $S_T$  remained nearly temperature independent for some lower concentrations (0.019 wt and 0.020 wt), while for higher concentrations  $S_T$  showed a pronounced change in the slope at 28 °C for 0.023 wt or 36 °C for 0.021 wt. At these temperatures, the Soret coefficient started to increase. This indicated that larger micellar aggregates contributed to the thermal diffusion properties. Because the formation of micelles is a continuous process, it was assumed that the number of micelles increased slowly with temperature above the *cmc* and the influence on the thermal diffusion behavior was continuously strengthened. The existence of micelles at higher temperatures was also observed in the mass diffusion coefficient. Due to a general decrease in viscosity with increasing temperature,  $D$  should increase almost linearly with temperature [330,331] as it was indicated by the 0.019 wt sample. In contrast, the samples of higher concentrations showed an almost temperature independent behavior and it was assumed that the increase of  $D$  was suppressed by the presence of micelles.

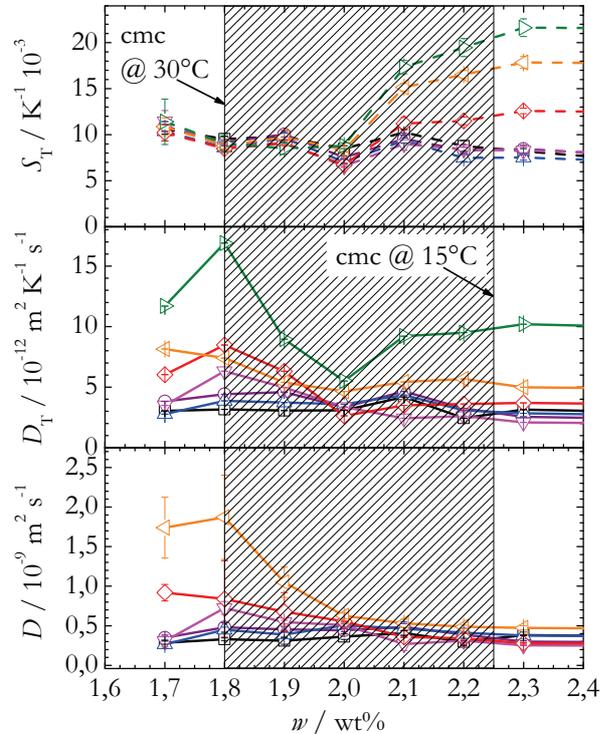

Fig.5.4 shows the concentration dependence of  $S_T$ ,  $D_T$  and  $D$ . In this plot, the location of the *cmc* is not so obvious as in Fig.5.3. The Soret coefficient showed a constant and concentration independent behavior for all temperatures below 0.020 wt. Above this concentration, the Soret coefficient, measured at higher temperatures, showed a pronounced increase. For the 60 °C-curve the Soret coefficient increased by a factor of two while below 40 °C the Soret coefficient remained constant at higher concentrations. The mass diffusion coefficient gave only evidence for the *cmc* for the two highest temperatures at 50 °C and 60 °C for which  $D$  dramatically decreased between 0.018 wt and 0.02 wt. All other temperature curves indicated equal mass diffusion coefficients which were almost concentration independent. The thermal diffusion coefficient showed no clear concentration dependence behavior.

In Figs.5.5 and 5.6 the hydrodynamic radius is shown in dependence of temperature and concentration, respectively. It should be mentioned that in the vicinity of the *cmc* the determined hydrodynamic radius was not a measure of the size of micelles, but it is an averaged radius of two contributions, which originated from molecules and micelles. At higher concentrations, the micellar contribution prevailed. The determined radii grew with increasing temperature and concentration. Again, for concentrations close to the *cmc* like 0.023 wt, the formation of micelles was indicated by a pronounced increase of the radius at 28 °C from 0.5 nm to 1.3 nm. At higher concentrations above 0.067 wt where the number

**Figure 5.3.:** The Soret, thermal diffusion and mass diffusion coefficients of  $C_7G_1/H_2O$  versus temperature. The concentrations are close to the cmc: 0.019 wt (squares), 0.020 wt (circles), 0.021 wt (triangle up), 0.022 wt (triangles down) and 0.023 wt (triangles left). The determined critical micelle concentrations are marked by vertical dotted lines.

density of micelles and thus their contribution to the radius was larger, the measured radii of 2.3 nm agreed with the estimated hydrodynamic radius of spherical micelles calculated from the length of a surfactant molecule including a hydrogen layer around the micelle of 0.5 nm. In the higher concentration regime above 0.067 wt, the hydrodynamic radius became almost independent from temperature and concentration. Thus, it was assumed that in the higher concentration regime up to a surfactant mass fraction 12 % an increase in concentration led to an increase in the number density of micelles. Interparticle interaction effects contributing to the thermal diffusion properties [42] were not observed.

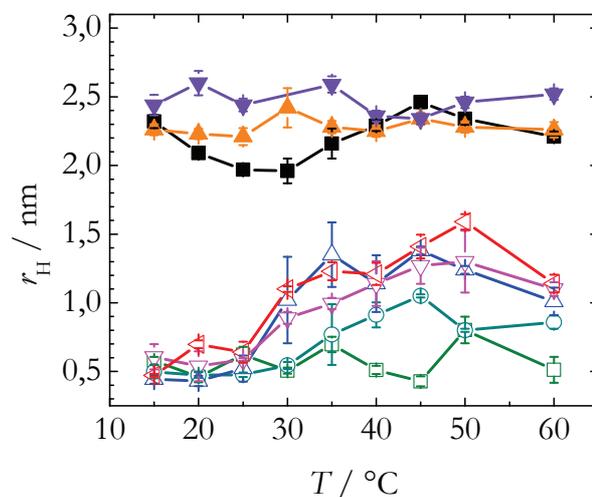

**Figure 5.4.:** The Soret, thermal diffusion and mass diffusion coefficients of  $C_7G_1/H_2O$  versus concentration. The temperatures are 15 °C (squares), 20 °C (circles), 25 °C (triangles up), 30 °C (triangles down), 40 °C (diamonds), 50 °C (triangles left) and 60 °C (triangles right). The shaded area marks the range wherein the cmc is found for temperatures between 15 °C and 30 °C.

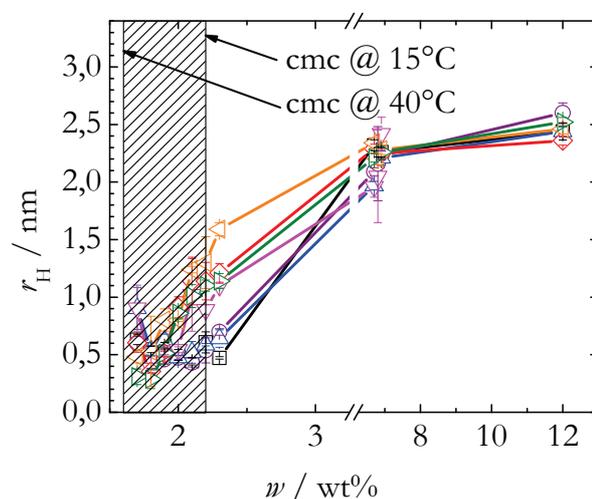

### 5.2.2. Soret Coefficient of $C_8G_2/H_2O$ Mixtures

The determination of the *cmc* of the aqueous  $C_8G_2$  system using surface tension methods was problematic, so that we investigated the thermal diffusion properties in a concentration range, which we estimated using literature values. The *cmc* is approximately at 0.0087 wt (25 °C) [239]. We also performed thermal diffusion measurements at concentrations around 0.002 wt, which corresponds to our determined *cmc*.

Fig.5.7 shows the Soret coefficient versus temperature for several concentrations in the vicinity of the *cmc*. For all concentrations, which were expected to lie below the *cmc*, no temperature dependence was observed and the Soret coefficient remained constant at  $0.01 \text{ K}^{-1}$  which is equal to the values determined for the  $C_7G_1$  and  $C_8G_1$  solutions below the *cmc* in Figs.5.4 and 4.7, respectively. For concentrations above 0.01 wt,  $S_T$  showed

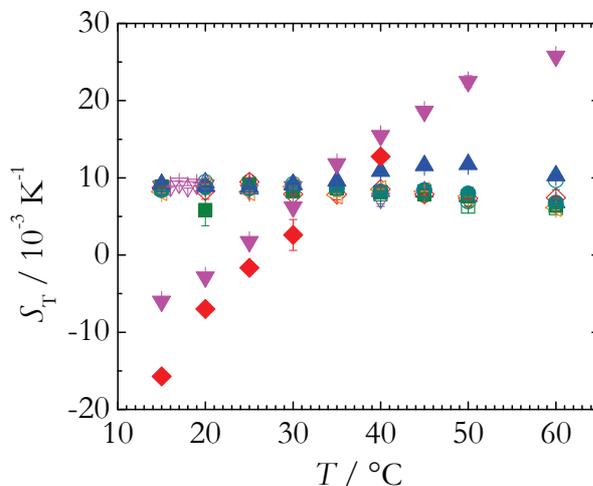

**Figure 5.5.:** The hydrodynamic radius versus temperature of  $C_7G_1/H_2O$ . The concentrations close to the cmc are: 0.019 wt (squares), 0.020 wt (circles), 0.021 wt (triangle up), 0.022 wt (triangles down) and 0.023 wt (triangles left). Higher concentration: 0.067 wt (solid squares), 0.069 wt (solid triangles up) and 0.12 wt (solid triangles down).

**Figure 5.6.:** The hydrodynamic radius versus the surfactant mass fraction of  $C_7G_1$ . The temperatures are 15 °C (squares), 20 °C (circles), 25 °C (triangles up), 30 °C (triangles down), 40 °C (diamonds), 50 °C (triangles left) and 60 °C (triangles right).

a pronounced temperature dependence: The Soret coefficient increased with increasing temperature and the slope became steeper with increasing concentration. The two highest

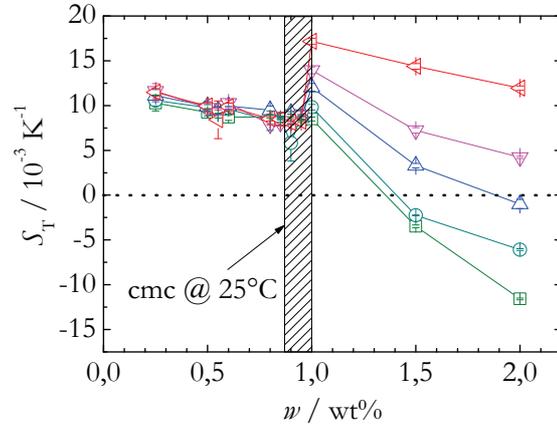

**Figure 5.7.:** The Soret coefficient versus temperature of  $C_8G_2/H_2O$ . The concentrations are 0.005 wt (open squares), 0.0055 wt (open circles), 0.006 wt (open triangles up), 0.007 wt (open triangles down), 0.008 wt (open diamonds), 0.0085 wt (open triangles left), 0.009 wt (filled squares), 0.0095 wt (filled circles), 0.01 wt (filled triangles up), 0.015 wt (filled triangles down) and 0.02 wt (filled diamonds). Referring to literature values, the filled symbols mark concentrations above the cmc while open symbols represent concentrations below the cmc.

concentrations at 0.015 wt and 0.02 wt showed even a sign change of  $S_T$ , which will be discussed in Sec.5.3.1.

Fig.5.8 shows the concentration dependence of  $S_T$  at different temperatures. Above 0.01 wt, a strong increase of  $S_T$  was observed, if the temperature was higher than 25 °C. For lower temperatures,  $S_T$  started to decrease. To our best knowledge, this abrupt change of the Soret coefficient indicated the *cmc*. For further increasing concentration,  $S_T$  decreased slightly and changed sign from positive to negative for temperatures below 25 °C in this concentration regime (see Sec.5.3.2).

### 5.3. Sign Inversion Behavior

All sugar surfactants showed a sign inversion of  $S_T$  and  $D_T$  above the *cmc* at low temperatures. In the following, the temperature and concentration dependence of the sign inversion will be discussed.

**Figure 5.8.:** The Soret coefficient versus the surfactant concentration of  $C_8G_2/H_2O$ . The temperatures are 15 °C (squares), 20 °C (circles), 25 °C (triangles up), 30 °C (triangles down), 40 °C (triangles left).

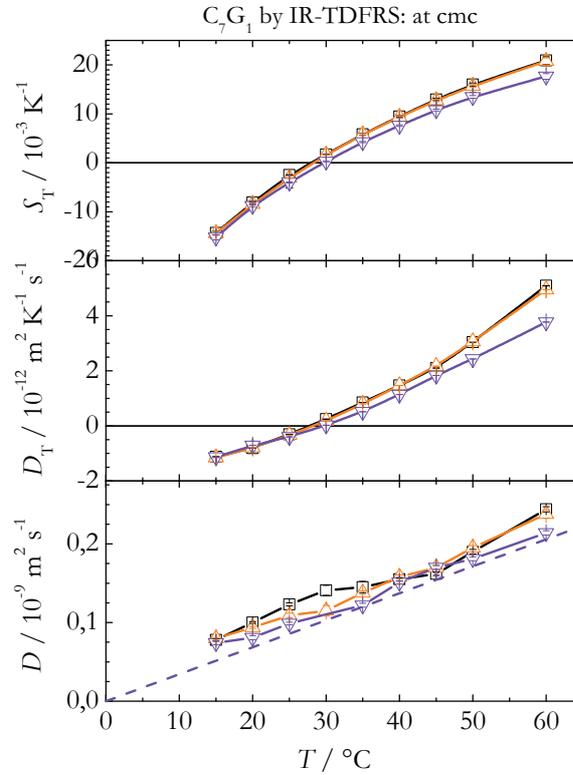

### 5.3.1. Sign Inversion in a Temperature Dependence

In Fig.5.9 the temperature dependence of the Soret and the diffusion coefficients of  $C_7G_1$  is shown. For all concentrations the sign inversion from negative to positive with increasing temperature occurred. The sign inversion temperature is almost the same for the investigated concentrations and was slightly below 30 °C. The Soret coefficient indicated that it approaches a constant value at infinite temperatures. A similar result was found for  $C_8G_2$  (Fig.5.7) and  $C_8G_1$  (Fig.4.11) but in these systems, the sign inversion temperature spreads over a temperature range of approximately 5 K in the investigated concentration range.

The comparable thermal diffusion behavior of the three investigated sugar surfactants led to the question, if these properties could be described using a general expression. Iacopini *et al.* [33,64] introduced an empirical function to describe the sign inversion temperature dependence:

$$S_T(T) = S_T^\infty(T) \left( 1 - \exp \left[ \frac{T^\pm - T}{T_0} \right] \right) \quad (5.3)$$

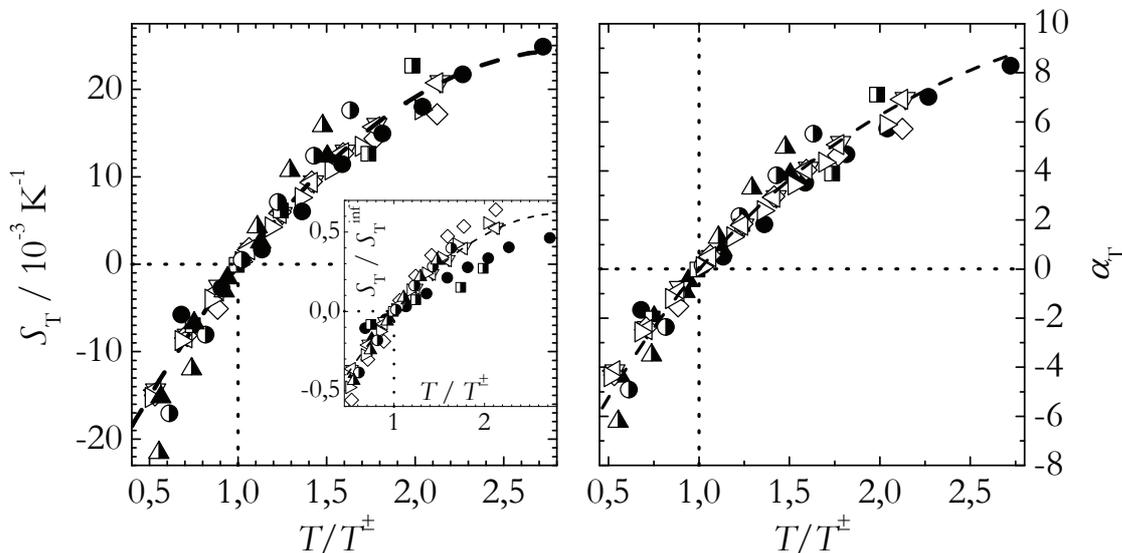

where  $S_T^\infty$  is the Soret coefficient at high temperatures,  $T^\pm$  is the sign inversion temperature and  $T_0$  is a measure for the strength of temperature effects. Eq.5.3 was not applicable for the sugar surfactant systems because at high temperatures deviations from the estimated master curve occurred such that the data points referring to  $C_7G_1/H_2O$  were much

**Figure 5.9.:** The Soret coefficient of  $C_7G_1/H_2O$  solutions versus temperature. The concentrations are: 0.067 wt (squares), 0.069 wt (triangles up) and 0.12 wt (triangles down). Dashed lines are guides to the eye.

larger and data points referring to the  $C_8G_1/H_2O$  system lay below the master curve (see inset of left Fig.5.10). In contrast, the plot of the (non-normalized) Soret coefficient versus the normalized temperature showed a less pronounced data spreading below 10 % (see left Fig.5.10).

A different approach was introduced, which considers the product of the Soret coefficient and the temperature. The product is the thermal diffusion factor  $\alpha_T = TS_T$ . In the right plot of Fig.5.10  $\alpha_T$  is plotted versus the normalized temperature,  $T/T^\pm$ , and a good correlation among the investigated surfactant solutions was found within the error bars which are not shown for clarity.

**Figure 5.10.:** *Left:* The Soret coefficient of all investigated sugar surfactant solutions versus the normalized temperature. *Inset:* normalization using the empirical Eq.5.3 [48]. *Right:* The thermal diffusion factor versus the normalized temperature. The dashed line marks the averaged master curve. The sign change of  $\alpha_T$  occurs at  $T/T^\pm = 1$ .

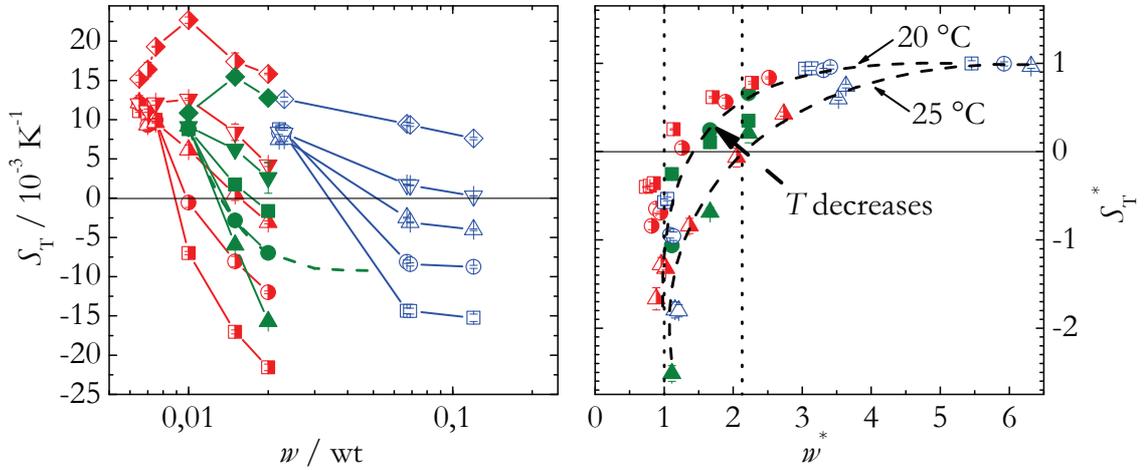

### 5.3.2. Sign Inversion in a Concentration Dependence

As already discussed (c.f. Figs.4.3.3 and 5.8) the Soret coefficient decays generally with concentration for surfactant mass fractions which were much higher than the  $cmc$ . The decrease became steeper with decreasing temperature. At a certain concentration,  $w_\pm$ ,  $S_T$  turned from positive to negative. The sign change concentration shifts to lower concentrations if the temperature is decreased. For instance for the  $C_7G_1$  system,  $w_\pm$  was shifted from 0.06 wt (25 °C) to 0.04 wt (15 °C).

It was assumed that to a certain extend the sign inversion should correlate with the  $cmc$  as both effects originate from solute-solvent interactions. Therefore, the Soret coefficient and concentration were scaled by

$$S_T^*(T) = S_T(T)/S_T^{w,inf}(T) \quad \text{and} \quad w^*(T) = w/w_{cmc}(T), \quad (5.4)$$

with the Soret coefficient at infinite concentrations,  $S_T^{w,inf}$ , and the critical micelle concentration,  $w_{cmc}$ . Normalized values are superscripted with a star. Eq.5.4 allowed to

**Figure 5.11.:** *Left:* Comparison of  $S_T$  versus the surfactant concentration. The surfactants:  $\text{C}_7\text{G}_1$  (open, blue),  $\text{C}_8\text{G}_1$  (open-filled, red),  $\text{C}_8\text{G}_2$  (filled, green). Temperatures: 15 °C (squares), 20 °C (circles), 25 °C (triangles up). *Right:* The normalized Soret coefficient versus the concentration in scales of the cmc.

express the concentration as a multiple of the critical micelle concentration, and  $S_T$  was normalized with respect to an infinite value at high concentrations.  $S_T^{w,inf}$  was obtained by an exponential fit to the  $S_T(w)$ -curves (dashed line in the left plot of Fig.5.11).

In the left plot of Fig.5.11 the investigated surfactant systems are compared by means of their Soret coefficient which was measured at concentrations above the *cmc*. These data were normalized using Eq.5.4 and are shown in the right plot of Fig.5.11: All measured Soret coefficients of the surfactant systems lay on isotherms. The normalization forced these isotherms to start at  $w^* = 1$  at low values of  $S_T^*$ , and to end in the high concentration regime at  $S_T^* = 1$ . Regarding the isotherm at 20 °C or 25 °C, it was observed that the isotherm of the lower temperature converged faster against  $S_T^*$ . This confirmed also the previous observation that the sign inversion occurred at lower concentrations if the temperature was lower. For instance by decreasing the temperature by 10 K the sign inversion concentration was almost halved. The normalization of the concentration also indicated that the ratio  $w_{\pm}/w_{cmc}$  is almost equal for the investigated sugar surfactant systems under isothermal conditions.

## 5.4. Dependence on the Ratio of Viscosity and Thermal Expansion Coefficient

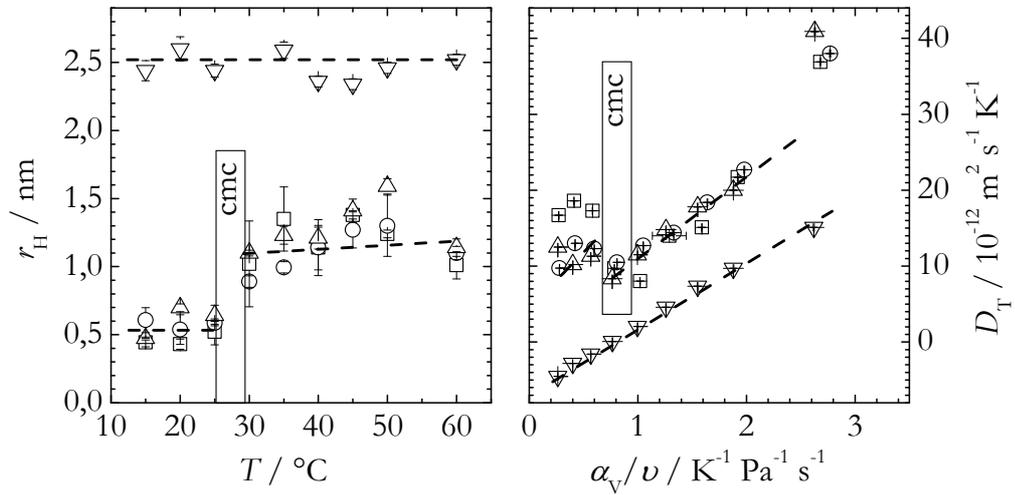

For aqueous solutions of monosaccharides and oligosaccharides, the thermal diffusion coefficient depends linearly on the ratio between the thermal expansion and the kinematic viscosity [60, 332, 333]. Also theoretically a linear relation between  $D_T$  and  $\alpha_V$  is expected [334]. The viscosity,  $\eta$ , and the thermal expansion coefficient,  $\alpha_V$ , are parameters which characterize the solvent [335, 336].

The question arose if also the surfactant systems under investigation show a similar behavior in the micellar state above the *cmc*. This might be reasonable, as the surfactant systems are to a certain extent comparable to the sugar systems, because the surfactant micelles interact with the solvent via the glycoside head group units. The viscosity (using a Anton Paar AMVn viscometer), density (using a Anton Paar DMA 4500 densimeter) and thermal expansion coefficient of the  $C_7G_1/H_2O$  system were determined for several concentrations from 2.1–12 wt%. The IR-TDFRS measurements indicated that for equimolar concentrations, the hydrodynamic radii of the micelles did not change with temperature (left plot in Fig.5.12) except at the *cmi*. On the other hand, we know that with increasing temperature, the hydrogen bonds break. Hence, the temperature was used as a tool to tune the micelle-solvent interactions.

The right plot in Fig.5.12 shows the thermal diffusion coefficient as a function of the ratio between the thermal expansion coefficient and the viscosity for several concentrations of  $C_7G_1$ . A linear dependence of  $D_T$  on the ratio of  $\alpha_V/\eta$  was found for the low concentrated systems above the *cmc*. For the highest measured solution at 12 wt%, deviations from the linearity are observed. A similar observation has been made for sugar solutions, so that we assume, that interactions are responsible for the deviations.

## 5.5. Comparison with Literature Results

The most investigated sugar surfactant is  $C_8G_1$ . Other sugar surfactants were rarely investigated. Therefore, this section will emphasize on two interesting studies on  $C_8G_1/H_2O$  systems which were assumed to shed some light on the observed sign inversion of the Soret coefficient. Unfortunately, these studies did not investigate the entire temperature and

**Figure 5.12.:** *Left:* The hydrodynamic radius versus temperature of  $\text{C}_7\text{G}_1/\text{H}_2\text{O}$  for the concentrations: 2.1 wt% (squares), 2.2 wt% (circles), 2.3 wt% (triangles up) and 12 wt% (triangles down). The white box marks the cmc for the three lowest concentrations. **Right:** The thermal diffusion coefficient versus the ratio  $\alpha/\nu$  of  $\text{C}_7\text{G}_1/\text{H}_2\text{O}$  in a concentration range between 2.1 wt% and 12 wt%.

concentration range of this work so that the following discussion needs to be critically scrutinized.

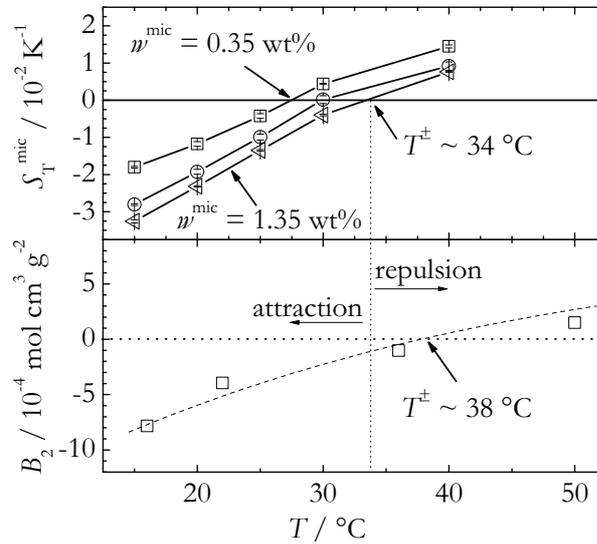

Kameyama and Takagi [212] reported a sign change of the second virial coefficient for  $C_8G_1$  for a concentration slightly above the *cmc* at 1.2 wt% from negative to positive with increasing temperature. The sign change temperature was found at 38 °C. The virial coefficient is directly related to the intermolecular potential [337]. A positive virial coefficient indicates repulsion and a negative attractive interaction potentials [338], respectively. Thus, a change in the virial coefficient indicates changes in the particle-solvent interactions. In the case of the investigated surfactant systems, it was assumed that these are micelle-solvent interactions. To compare our thermodiffusion measurements with the findings by Kameyama and Takagi, we had to separate the micellar contribution of the Soret coefficient,  $S_T^{\text{mic}}$ , from the molecular contribution,  $S_T^{\text{mol}}$ , like:

$$S_T = S_T^{\text{mol}} + S_T^{\text{mic}} . \quad (5.5)$$

Then,  $S_T^{\text{mic}}$  of  $C_8G_1$  was plotted versus the micelle concentration,  $w - w_{\text{cmc}}$ , in Fig.5.13.  $S_T^{\text{mic}}$  changed sign at a micelle concentration of 1.35 wt% and a temperature of 34 °C which agreed with the sign change of the virial coefficient at 1.2 wt% (38 °C) within the error bars.

In a second discussion, we shed some light on the micelle-solvent interface. It was reported that the hydrophilic head group of the sugar surfactants allows high hydration numbers per head group. Pastor *et al.* [317] determined the hydration number,  $n_h$ , for  $C_8G_1$  solutions at 25 °C in a concentration regime close to the *cmc*. The bottom plot in Fig.5.14 shows their results: Below the *cmc*, the hydration number per molecule is 16 and independent from concentration. Above the *cmc*, where some surfactant molecules are assimilated into micelles, the hydration number decreases. This is caused by the preferential hydrogen bonding of the bonded surfactant molecule in a micelle with its neighboring surfactant molecules rather than with the water molecules. We compared the hydration number with the Soret coefficient. In the top plot of Fig.5.14, the concentration dependence of the Soret coefficient, also measured at 25 °C, is shown. It was observed that  $S_T$  and the hydration number showed almost the same trend in the investigated concentration regime. A sign inversion of  $S_T$  was observed at a concentration, where the hydration number had decayed to the half of the initial value at the *cmc*. A parametric plot of  $n_h$  and  $S_T$  indicated a quadratic dependence (inset in Fig.5.14).

Finally, this comparison confirmed the assumption that the Soret coefficient changes sign

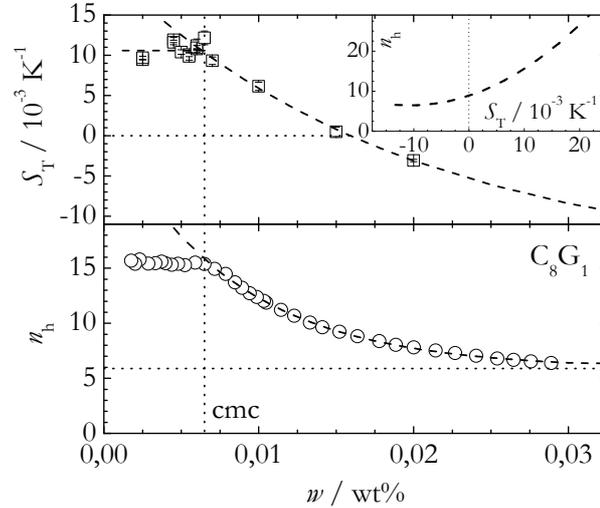

**Figure 5.13.:** Top: The micelle-micelle contribution of the Soret coefficient,  $S_T - S_T^{\text{mol}}$ , versus the concentration of micelles,  $w - w_{\text{cmc}}$ . The sign change is approximately at 34 °C which correlates with the sign change of the second virial coefficient determined by Kameyama and Takagi [212] for a 1.2 wt% sample at 38 °C (bottom).

from negative to positive when the solvent quality becomes bad, because a change in the solvent quality also causes the decrease of hydrated water molecules per surfactant molecule.

## 5.6. Conclusion

Surface tension measurements were used to determine the  $cmc$  of three sugar surfactants. The measurements produced reliable results for  $C_7G_1$  and  $C_8G_1$  but failed for  $C_8G_2$ . Comparing the  $cmc$  of  $C_7G_1$  and  $C_8G_1$ , it was indicated that the temperature dependence of the  $cmc$  is more pronounced with decreasing carbon chain length.

Then it was shown that the determined  $cmc$  is visible in TDFRS measurements by an abrupt change of the Soret coefficient which is caused by the influence of micelles on the thermal diffusion behavior. In the temperature dependence, a pronounced change in the slope of  $S_T$  at the  $cmc$  was observed, while in the concentration dependence  $S_T$  showed an abrupt change. Below the  $cmc$  the Soret coefficient was almost independent from temperature or concentration in the molecular regime. It turned out that the  $cmc$ ,

**Figure 5.14.:** Top: The Soret coefficient versus the concentration determined by IR-TDFRS. Bottom: The hydration number per surfactant molecule versus the concentration by Pastor [317]. Inset: The hydration number depends quadratically on the Soret coefficient. Dashed lines are fits, dotted lines are guides to the eyes.

determined by surface tension measurements, was approximately 20 % lower than the *cmc* measured in TDFRS. This was reasonable since in TDFRS we measured in the bulk phase and detected the contribution of the formed micelles, whereas the surface tension measurements determined the wetting of the surface. Although it was not possible to determine the *cmc* of  $C_8G_2$  by surface tension measurements, we observed a pronounced change in the thermal diffusion behavior at 0.01 wt which was approximately 20 % higher than the literature value at  $T = 25$  °C. Regarding the impurities in  $C_8G_2$  (see also App. E), we expected that they were surface-active, rather nonionic than ionic, and did not alter the thermal diffusion properties in the bulk phase. Unfortunately, the TDFRS data did only allow to identify a temperature dependence of the *cmc* for the  $C_7G_1$  solutions.

Above the *cmc*, the concentration dependence of the Soret coefficient was different for the low temperature and the high temperature measurements. The dramatic increase of  $S_T$  with increasing concentration was only observed for temperatures above 25 °C, while below this temperature,  $S_T$  decreased above the *cmc*. This might be reasonable by a lowered solvent quality at lower temperatures. Also the sign inversion concentration was shifted to lower concentrations if the temperature was lower. The sign change could be attributed to a decrease in the solvent quality, which was also indicated by an decrease of

the hydration number with concentration by Pastor *et al.* [317]. A comparison with the second virial coefficient indicated that at the sign inversion the interaction forces turned from attraction ( $S_T < 0$ ) to repulsion ( $S_T > 0$ ).

An empirical approach was found, to describe the temperature dependence of the  $S_T$  sign inversion by a master curve using a dimensionless temperature and the thermal diffusion factor,  $\alpha_T$ . Previously introduced empirical approaches by Iacopini *et al.* were not successful.

It was also demonstrated that the sign inversion concentration was, to a certain extent, correlated with the *cmc*. By normalizing of the Soret coefficient and expressing the concentration in scales of the *cmc*, isotherms were obtained. They indicated that at constant temperature the ratio between the *cmc* and the sign inversion concentration was almost the same for the investigated sugar surfactant systems.

## MICROEMULSIONS AS MODEL SYSTEMS FOR SPHERES

We use microemulsion droplets as hard-sphere particles to investigate the radial dependence of the Soret coefficient. These droplets can be easily varied in size and shape by concentration and temperature, respectively. Thus, by changing physical parameters, we tune the droplet style while keeping the surface properties untouched. This is the general advantage in comparison to synthesized colloidal particles for which it is not possible to reproduce the same grafting or charge density of the colloidal particle. Therefore, the behavior of the colloidal particles is not solely influenced by a change in radius, but also by the surface properties of the colloid. The radial dependence of  $S_T$  of colloidal particles has already been studied by several authors [65–67, 99]. Presently it is discussed whether the Soret coefficient depends linearly or quadratically on the particle radius.

A quadratic dependence was observed by Duhr and Braun [65], linear scaling properties are found by Putnam and Cahill [67] for an aqueous solution of carboxyl functionalized polystyrene (PS) spheres and proteins of T4 lysozyme using a microfluidic beam deflection technique. Also Vigolo *et al.* [35] obtained a linear dependence investigating microemulsion droplets with ionic dioctyl sodium sulfosuccinate (AOT) as surfactant, as well as Braibanti *et al.* [66] for polystyrene spheres in 1 mM Tris-HCl buffer. A review was written by Piazza and Parola [99]. Recently, Vigolo *et al.* [33] observed a linear dependence of the thermophoretic mobility,  $D_T$ , versus the Debye length for sodium dodecyl sulfate (SDS) solutions. Theoretical approaches are given by Würger [339] predicting a linear radial dependence for solid particles and a quadratic one for soft particles.

## 6.1. Experiment and Data Analysis

### 6.1.1. Sample Characterization

We used ultrapure Milli-Q water (Millipore, USA). The surfactant monododecyl pentaethylene glycol (C<sub>12</sub>E<sub>5</sub>) was purchased from Nikkol with a purity > 98%. As hydrophobic component, we chose *n*-alkanes: *n*-octane, *n*-decane, *n*-dodecane and *n*-tetradecane. All *n*-alkanes are products of Sigma-Aldrich with a purity ≥ 98%. The *n*-alkanes and the nonionic surfactant C<sub>12</sub>E<sub>5</sub> were used without further purification. Before the mixtures were prepared, the surfactant was tested for contamination by determining the cloud point. We determined the cloud point of  $T_{cp} = (31.40 \pm 0.05)$  °C which agrees with values given by Schubert *et al.* [340] who determined a cloud point temperature of 32.0 °C. This indicates that impurities are negligible.

The refractive indices, boiling and freezing points of the used substances are given in Tab.6.1. The refractive index of the *n*-alkanes and surfactant is higher than the refractive index of water, which results in a sufficient contrast in the TDFRS experiments if o/w-microemulsions are investigated. The solubility of the *n*-alkanes in water is negligible: *n*-octane has the highest solubility of 0.7 mg/l (20 °C [341]). With increasing alkyl chain length the solubility decreases.

Hellma flow cells with an optical path length of 0.2 mm were used in classical TDFRS and IR-TDFRS. The microemulsions were directly filled into the cell. The mixtures were thermostated beforehand in a temperature controlled water bath ( $\Delta T = \pm 0.1$  K) for several hours under continuous stirring to ensure that the microemulsions are in the  $1\phi$  state.

**Table 6.2.:** Determination of the *efb* and *ncb* temperatures for each microemulsion system for a given oil concentration, w<sub>B</sub>. The droplet concentration, w<sub>0</sub> in mass fraction or ϕ<sub>0</sub> in volume fraction, results from the additional amount of water in the microemulsion.

The water bath temperature was set to a value which corresponds to a temperature in the 1ϕ funnel on the water-rich side of the phase diagram close to the *efb*. In a controlled temperature environment, the mixture was transferred into the thermal equilibrated flow cells. To ensure that the sample was still in the 1ϕ regime, we measured the scattered light intensity in the IR-TDFRS setup which is by magnitudes higher once the sample has entered the upper or lower 2ϕ region.

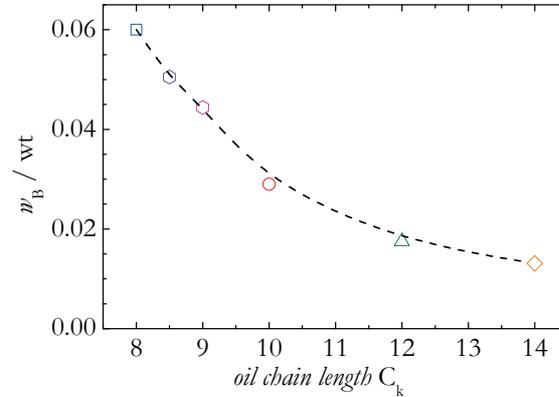

### 6.1.2. Determination of the Phase Transition Boundaries

As already illustrated in Fig.2.4 and Fig.6.1 the phase diagram of microemulsions studied via a  $T(w_B)$ -section through the phase prism is characterized by a 1ϕ funnel which is confined by the lower *efb* and the upper *ncb*. For temperatures below the *efb* in the 2ϕ region a microemulsion phase coexists with an oil excess phase, while at higher temperatures the *ncb* delimits the 1ϕ region. Above this boundary different phases can be found which are defined here as  $\bar{2}\phi$  phase.

In order to determine the temperature-oil concentration dependence ( $T(w_B)$ ) of the *efb* and *ncb* we investigated the phase transition from 2ϕ to 1ϕ as it is described in the following: In the case of the *efb*, we kept the sample at  $T < T_{efb}$  in the 2ϕ region in a water bath, whereas the temperature inside the water bath was measured directly at the sample holder. The sample was equilibrated in the water bath at constant temperature and continuous stirring for four minutes (long-chained *n*-alkane solutions: eight minutes) and then we checked visually if the sample was in 1ϕ or 2ϕ. Was the sample still in the 2ϕ region we increased the temperature further until we reached the 1ϕ region. If

**Figure 6.1.:** Determination of the  $1\phi$  regions of the microemulsions under investigation of the type  $H_2O/C_x/C_{12}E_5$  on the water-rich side with  $\gamma_a = 0.03$  wt. The temperature is plotted versus the n-alkane concentration,  $w_B$ . The points mark measured phase transition temperatures, the lines are guides to the eyes. The stars represent the concentrations at similar efb temperatures which are given in Tab.6.2 and were taken for the IR-TDFRS measurements. From top to bottom: n-tetradecane ( $w_B = 0.0131$  wt), n-dodecane ( $w_B = 0.0191$  wt), n-decane ( $w_B = 0.029$  wt), mixtures of n-octane/n-decane in a 50/50-ratio ( $w_B = 0.0444$  wt, lilac) and in a 75/25-ratio ( $w_B = 0.0505$  wt, purple), and n-octane ( $w_B = 0.060$  wt), respectively. The mixed n-alkane systems had a ratio of 50/50 (lilac) and 75/25 (purple).

**Figure 6.2.:** The  $k$ -alkane mass fraction  $w_B$  is plotted versus the carbon chain length of the  $k$ -alkanes at the determined  $efb$  temperature (see Tab.6.2). The data points at  $C_k = 9$  and  $C_k = 8.5$  are mixed alkane systems with a mass ratio of 50/50 and 75/25 of  $n$ -octane and  $n$ -decane. Symbols are used as given in Fig. 6.1.

the last temperature step was larger than  $\Delta T = 0.1$  K, we had to bring the sample back into  $\underline{2}\phi$  region and to restart with smaller temperature steps. The sample was quickly cooled down to  $T = -17$  °C and then warmed up to a temperature within the  $\underline{2}\phi$  region. Sometimes this freezing procedure had to be repeated several times for the long-chained  $n$ -alkane systems, until the sample entered the  $\underline{2}\phi$  region.

This way, we approached the  $efb$  temperature iteratively and determined the transition temperature with an accuracy of  $\Delta T = \pm 0.15$  K. The  $ncb$  was determined in a similar way starting in the  $\bar{2}\phi$  region and lowering the temperature till the  $ncb$  was reached.

Fig.6.1 shows the funnels on the water-rich side for four different pure  $n$ -alkanes and two  $n$ -alkane mixtures. With decreasing chain length of the  $n$ -alkane the funnel become narrower and the funnel shifts towards a higher oil content. Hence, the accessible temperature range in the  $1\phi$ -region shrinks with decreasing chain length of oil component, which complicates the measurements for short  $n$ -alkanes. For  $n$ -octane the funnel width is only 2 K at  $w_B = 0.060$  wt. As can be seen in Fig.6.2 the  $n$ -alkane concentration is being reduced by a factor of two, when chain length is increased by two C-atoms under the condition to find the  $efb$  at the same temperature.

### 6.1.3. General Considerations about the Characterization of the Microemulsion Droplets

In order to study the radial dependence of the microemulsion droplets we need to be sure to have spherical aggregates. The question is how close do we have to select the temperature to the *efb* in order to measure and work with spherical microemulsion droplets. On the oil-rich side the formation of network like structures leads to a pronounced increase in the conductivity [344]. Comparing with electric conductivity measurements [344] in microemulsions it seems to be reasonable to assume that the transition between spheres and cylindrical networks occurs in the first third of the temperature range between the *efb* and *ncb*.

We define our measurement range in the first third of the temperature range between the *efb* and the *ncb*, in which the spherical microemulsion droplets should dominate the behavior. Therefore, all measurements have been performed between  $\frac{1}{3}(2T_{efb} + T_{ncb})$  and  $T_{efb}$  which describes the first third of the  $1\phi$  funnel close to the *efb*. The data at the *efb* are obtained by extrapolation of measurements at different temperatures in the chosen temperature range. Analyzing the dynamic light and static neutron scattering experiments, we will later see, that the range depends on the *n*-alkane or rather on the distance to the tricritical point (c.f. section 6.3.1 and 6.3.3).

### 6.1.4. Refractive Index Increments

For the determination of the refractive index increments with temperature,  $(\partial n/\partial T)_{p,w}$ , Hellma absorption cells with an optical path length of 10 mm were used in the improved Michelson interferometer. The change in temperature was approximately 0.5 mK/s such that the microemulsion during the measurement was in thermal equilibrium. We repeated the measurements four times for each sample. During the measurement, the microemulsion was always in the  $1\phi$  state. A possible phase transition could instantaneously be observed by a decrease of the transmitted intensity.

The refractive index increment with concentration,  $(\partial n/\partial w)_{p,T}$ , was calculated from refractive index values, which were determined by an Abbe refractometer (Anton Paar, Austria). We determined the refractive index for a given concentration  $w_{B,0}$  at several temperatures within the  $1\phi$  regime. The relevant concentration,  $w$ , to determine  $(\partial n/\partial w)_{p,T}$ , is the mass fraction of the oil component,  $w_{B,0}$ , because the surfactant concentration is

kept constant. As illustrated in Fig.3.9 a direct measurement of the refractive index values at higher oil mass fractions,  $w_{B,0+\delta}$ , is not possible, because the system phase separates. The maximal  $\delta$  is in the order of 0.01 wt, whereas other concentrations are in between  $w_{B,0}$  and  $w_{B,0+\delta}$ . To overcome this problem, measurements of the refractive index values have to be extrapolated from measurements of the refractive index increments in the  $1\phi$  regime which were measured at higher temperatures at the concentration  $w_{B,0+\delta}$ . The concentration below  $w_{B,0}$  can be measured directly at the desired temperature and do not need to be extrapolated.

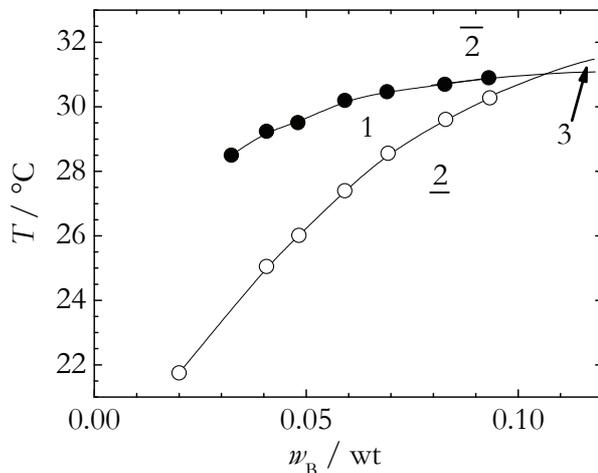

We observed that the thermodynamical inhibition of the microemulsion systems had a pronounced influence on the refractive index measurements: The sample took several minutes to equilibrate after changing the temperature in the refractometer. On the other hand, we had to minimize evaporation during the measurements by shortening the waiting time. To satisfy both demands, we worked with a sealed sample container and selected a minimum equilibration time until the refractive index was constant. To examine whether the sample suffers from evaporation during the measurement, we re-measured the first temperature at the end of a run and corrected the obtained refractive index data proportionally by this difference, if necessary. Each series was repeated three times.

To check whether the extrapolation of the refractive indices at higher concentrations  $w_{B,0+\delta}$  yields higher error, we compared the calculated  $(\partial n/\partial w)_{p,T}$ -values with a theoretical approach by Kerker [345], which is a prediction for a simple coated sphere of oil-swollen droplets. This approach is based on the dielectric constant,  $\epsilon$ , which is connected to the refractive index by  $\epsilon_i = n_i^2$  where  $i$  denotes the components water (A), oil (B) and surfactant (C). Our experimentally determined values agreed with the theoretical values within an averaged error of approximately 3.8 %.

## 6.2. $S_T$ of the n-octane Microemulsions

We investigated the Soret coefficient of n-octane microemulsion systems at constant surfactant to water ratio  $\gamma_a = 0.022$  wt in the  $1\phi$  region of the phase diagram as it is shown in Fig.6.3. The temperature and the oil mass fraction were varied.

IR-TDFRS measurements have been performed in such way, that the measurement started at a certain temperature where the microemulsion is found in the  $1\phi$  state. In a series of measurements, the temperature was lowered stepwise towards the *efb* temperature. The dependence of the measured Soret coefficient on the temperature is shown in Fig.6.4. At

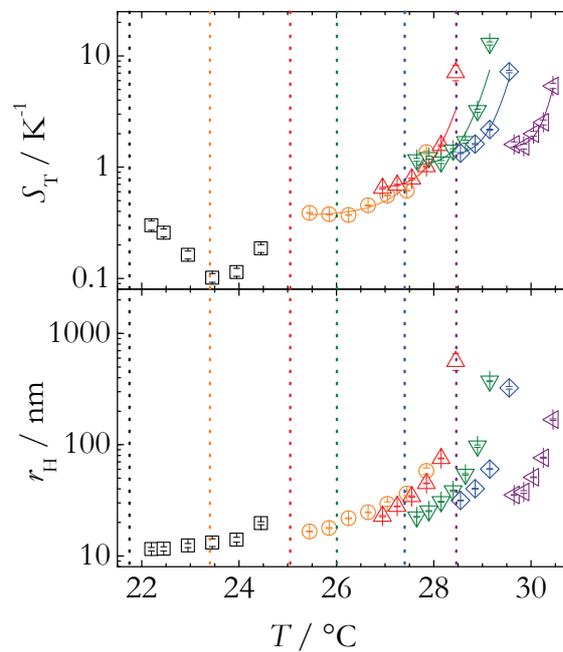

**Figure 6.3.:** The  $1\phi$  region on the water-rich side of the phase diagram of the  $H_2O/C_8/C_{12}E_5$  microemulsion with  $\gamma_a = 0.022$  wt.

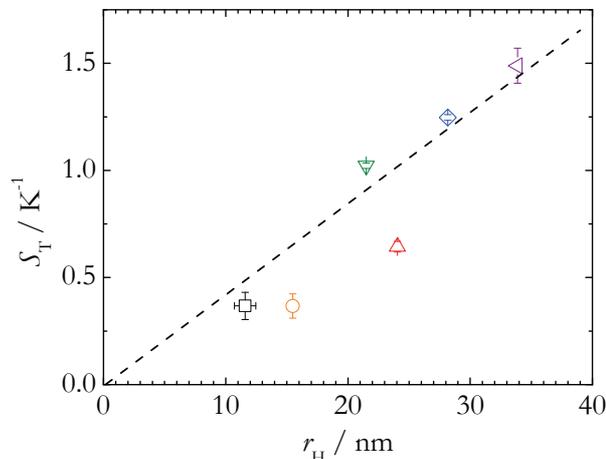

higher temperatures, the Soret coefficient diverged exponentially towards the  $ncb$  as the formation of network-like structures leads to slower diffusion processes. By decreasing the temperature, the Soret coefficient decreased and approached a plateau value at the  $efb$ .

In principle it is possible to study the radial dependence of  $S_T$  of a microemulsion, if one moves along the  $efb$  as depicted in Fig.6.3 for the system  $H_2O/C_8/C_{12}E_5$  by varying concentration and temperature, respectively. If one moves close to the  $efb$  the microemulsion droplets are assumed to be spherical [346,347] and their radius will increase with increasing oil fraction. But apart from the size change, also the temperature will change. Both effects will influence the Soret coefficient and it will be difficult to distinguish between both effects. Fig.6.5 shows the Soret coefficient extrapolated to the  $efb$  as function of the hydrodynamic radius, which was determined from the diffusion coefficient in the IR-TDFRS experiment using the Stokes-Einstein relation, in doing so interactions between the droplets are neglected. The description with a linear fit is rather pure taking into account the small investigated radial range from 11.6 nm to 33.9 nm, indicating that the neglect of changes of interactions and interfacial tension might not be justified.

From other studies of aqueous systems [62,153] we know that specific interactions such as hydrogen-bondings can influence the thermal diffusion properties strongly and even leads to sign changes of  $S_T$ . Also  $C_iE_j$  in  $H_2O$  shows dehydration effects with increasing temperature [348–350], therefore we expect also a temperature effect on  $S_T$ , if we study the radial dependence along the  $efb$ . Therefore, if we want to modify the radius, we need

**Figure 6.4.:** The Soret coefficient (top) and the hydrodynamic radius (bottom) are plotted versus the temperature for  $H_2O/C_8/C_{12}E_5$  microemulsions in the  $1\phi$  region determined by IR-TDFRS. Concentrations:  $w_B = 0.02$  wt (black squares),  $w_B = 0.03$  wt (orange circles),  $w_B = 0.04$  wt (red triangles top),  $w_B = 0.05$  wt (green triangles down),  $w_B = 0.06$  wt (blue diamonds), and  $w_B = 0.07$  wt (purple triangles left). The efb temperatures of the different microemulsions are sketched as vertical dotted lines in the respective colors.

**Figure 6.5.:** The Soret coefficient is plotted versus the hydrodynamic radius which was also determined from IR-TDFRS measurements. Symbols are used as given in Fig. 6.1. The dashed line indicates a linear size dependence of  $S_T$ .

to vary the oil component and the concentration of the oil component, so that the *efb* temperature is the same for different systems. To overcome the simultaneous temperature variation, when the radius was changed we used *n*-tetradecane, *n*-dodecane, *n*-decane, *n*-octane and mixtures of *n*-decane and *n*-octane with a mass ratio of 50/50 and 25/75, respectively. The corresponding  $1\phi$ -funnels for the pure *n*-alkane mixtures are shown in Fig.6.1.

### 6.3. $S_T$ of *n*-alkane Microemulsions

#### 6.3.1. SANS Measurements to check spherical Shape at the *efb*

We determined the size and shape of the microemulsion aggregates at the *efb* by small angle neutron scattering (SANS) measurements. For that purpose the group in Köln prepared  $D_2O/n$ -alkane/ $C_{12}E_5$  mixtures. The preparation with  $D_2O$  lowers the boundary temperature by approximately 2K [307] compared to the  $H_2O$  containing mixtures. Keeping the volume fraction constant, the mass fraction changes from  $\gamma_a = 0.03$  wt for the  $H_2O$  systems to  $\gamma_{a,d} = 0.0272$  wt for the  $D_2O$ -systems (see Tab.6.3). The phase boundaries of all samples are given in reference [277].

Before each measurement, the microemulsion and the sample cell were thermostated to a

<i>n</i> -alkane	$\phi_{c,i}$	$\phi_B$	$\phi_0$	$r_{SANS}$ [nm]	$t_{di}$ [nm]	$\sigma_G$ [nm]	$\phi_{mon,b}$	$d_{eff}$ [nm]

**Table 6.3.:** Results obtained from SANS measurements. The listed data are the surfactant volume fraction in the internal interface,  $\phi_c$ , the volume fraction of the n-alkanes,  $\phi_B$ , the droplet volume fraction,  $\phi_0$ , the mean droplet radius,  $r_{SANS}$ , the thickness parameter of the diffuse interface,  $t_{di}$ , the standard deviation of the Gaussian function describing the radius polydispersity around the mean droplet radius,  $\sigma_G$ , the monomeric dissolved C<sub>12</sub>E<sub>5</sub> in oil,  $\phi_{mon,b}$ , the effective diameter of the sticky hard spheres,  $d_{eff}$ .

temperature in the  $1\phi$  regime. The microemulsion was stirred meanwhile and subsequently filled into the sample cell. The distance between the microemulsion containing test tube and the sample cell was as short as possible to avoid temperature effects on the way. Then, the closed sample cell was left for five minutes in the thermostated water bath to equilibrate. We confirmed the state of the phase of the sample visually. The cell holder<sup>1</sup> in the beam line was thermostated to a temperature which is approximately 0.5 K higher than the *efb* temperature of the microemulsion. We measured the temperature precisely in the cell holder with a calibrated thermometer (Greisinger Electronic, High Precision digital Thermometer, GMH3710; with: PT100, GTF401,  $\Delta T = 1/10$  DIN between 0 – 100 °C) with an error of  $\pm 0.044$  K in this temperature range. Before transferring the sample cell to the cell holder we checked the microemulsion phase again. Once, the sample was fixed in the cell holder and the holder reached its final position for the measurement, we again checked the state of the phase of the microemulsion. We carefully lowered the temperature of the cell holder to the *efb* temperature to avoid phase separation. Finally, the shutter was opened and each sample was exposed to the neutron beam. The exposure times and collimator settings were chosen to achieve a sufficient signal to noise ratio and not to exceed the detector capacity. After data recording, we checked the phase of microemulsion visually in the cell holder but never found an indication for phase separation during the measurements.

Fig.6.6 shows the experimental scattering intensities  $I(q)$  after subtraction of the incoher-

<sup>1</sup>The cell holder provides space for four cells. Although only one cell is investigated, this holder provides a good thermal stability for the microemulsion sample due to its higher heat storage capacity.

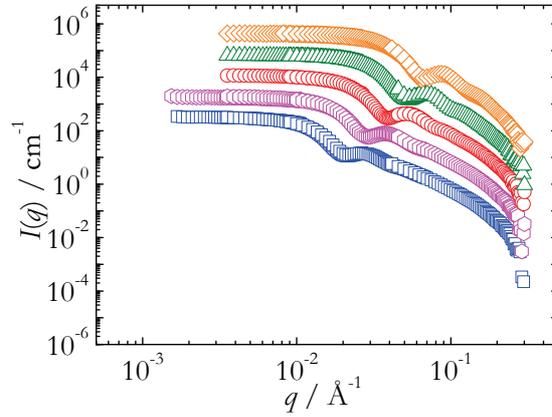

ent background as a function of the scattering vector  $q$  for  $D_2O/C_x/C_{12}E_5$  microemulsions. The scattering data have been described by a form factor for polydisperse spherical shells with a diffuse interface and core scattering [311]. The assumption for the structure factor  $S(q)$  being equal to one, leads to a systematically higher intensities than the experimental data points at low values of  $q$ , which indicates that interactions between the microemulsion droplets need to be considered.

These droplet interactions are included in the structure factor using a sticky hard spheres model [313,314]. The interactions were more pronounced for higher droplet concentrations which are found for microemulsion systems with the shorter  $n$ -alkanes, like  $n$ -octane with a droplet volume fraction of 11.15 vol%. The microemulsion droplets containing  $n$ -tetradecane has the smallest droplet volume fraction of 4.75 vol% and showed the smallest interaction effect. The strength of the interaction effects also influences the concentration dependence of the Soret coefficient, which is weak as long as the concentration is below 10 vol% [42, 327]. We determined a moderate polydispersity of  $(16.9 \pm 0.4)$  % of the mean droplet radii for all systems and an attractive region (effective sticky hard sphere diameter,  $d_{eff} = 2r_{SANS} + t_{di}$ ) of about 104 % ( $C_8$ ) to 114 % ( $C_{14}$ ) of the mean droplet diameter ( $2r_{SANS}$ ), respectively. The ratio of the hydrodynamic radius determined by IR-TDFRS and the mean droplet radius determined by SANS was for all systems  $r_H/r_{SANS} \approx 1.35 \pm 0.06$ .

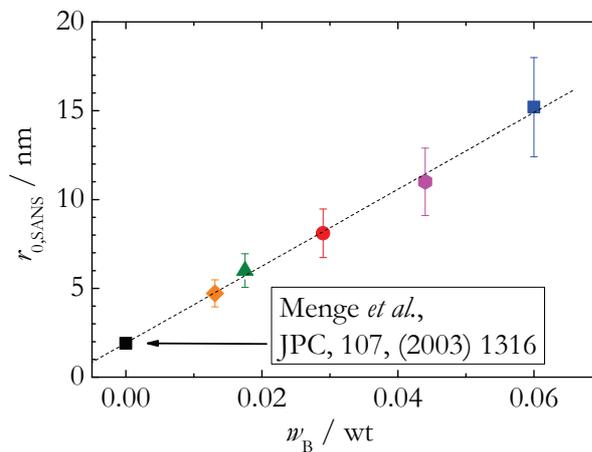

We extrapolated the determined mean droplet radii to zero oil concentration, which corresponds to a  $L_1$ -phase of the binary aqueous surfactant system [351], and find a droplet radius of 1.91 nm, which agrees with the value given by Menge *et al.* (see Fig.6.7). The authors investigated the cross sectional radius of gyration of this binary mixture with a mass ratio of  $C_{12}E_5$  to water of 7 mg/ml which is approximately four times lower than the ratio  $\gamma_a$  we worked with. Although, systems with different surfactant concentrations are being compared, the extrapolation of the droplet size yields a reliable result as the surfactant content influences the particle density but not the droplet size.

### 6.3.2. Measurement Procedure and Temperature Correlation

All samples were equilibrated in the lower part of the  $1\phi$  region and the sample holder in the IR-TDFRS setup was thermostated to the appropriate temperature of each microemulsion system in the  $1\phi$  region. The measurements started in the  $1\phi$  regime and ended at the *efb* or slightly below. Due to the fairly large size of the microemulsion

**Figure 6.6.:** SANS measurements were performed to determine the shape of the microemulsion aggregates at the efb temperature (see Tab.6.2). The scattered intensity is plotted versus the  $q$ -vector. The curves for different samples ( $C_8$ : squares,  $C_{8/10}$  (1:1): combs,  $C_{10}$ : circles,  $C_{12}$ : triangles up,  $C_{14}$ : diamonds) are shifted by a factor of ten on the logarithmic intensity scale.

**Figure 6.7.:** The mean droplet radius by SANS,  $r_{\text{SANS}}$ , is plotted versus the oil mass fraction. Symbols are used as given in Fig. 6.1. The data have been fitted linearly (dashed line) such that the extrapolation to  $w_B = 0.0$  wt gives the corresponding mean droplet radius for a water/surfactant solution which exactly fits with literature data by Menge et al. [352] (filled black square).

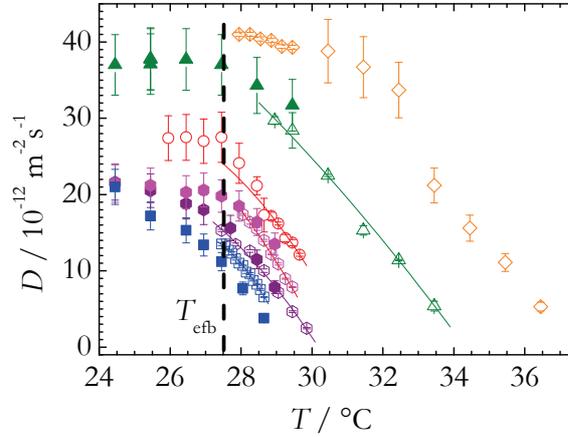

droplets in the range of up to  $r_H = 20$  nm, the diffusion coefficient was in the order of  $20 \cdot 10^{-12}$  m<sup>2</sup>/s. Thus, the measurements of each sample at different temperatures took up to five days for the slowest system with *n*-octane as oil component. During this long measurement time, the water content decreased slightly with time, so that the sample was shifted to a higher *n*-alkane content, which results in a higher *efb* temperature. To check for evaporation, a sample of H<sub>2</sub>O/C<sub>8</sub>/C<sub>10</sub>/C<sub>12</sub>E<sub>5</sub> (C<sub>8</sub>/C<sub>10</sub> = 75/25) was measured twice at 28.45 °C. Between both measurements, the cell was thermostated for almost 48 hours.  $S_T$  differs by  $0.00557$  K<sup>-1</sup>, which corresponds to an error of 2 %. The typical uncertainty of repeated measurements of  $S_T$  is in the order 9 %. Therefore the evaporation effect is negligible.

Additionally, the temperature in the sample was increased due to absorption of the laser light. This effect occurred locally and could not be detected by the temperature sensor in the cell holder. We specified this offset in the IR-TDFRS setup by measuring the intensity of the diffracted read-out laser in the vicinity of the phase transition boundary from  $1\phi$  to  $\bar{2}\phi$ . Therefore, we used a well known phase behavior of a H<sub>2</sub>O/*n*-octane/C<sub>10</sub>E<sub>4</sub> microemulsion with a mass ratio of H<sub>2</sub>O to C<sub>8</sub> of 50/50 and a concentration of the surfactant in water of  $\gamma_a = 0.154$  wt. This system is clear and transparent in the  $1\phi$  region but turns to be turbid in the  $\bar{2}\phi$  region where we measured a strong increase of scattering intensity in the setup (see Appendix C). The determined phase separation temperature by intensity measurements was  $\Delta T_{offset} = 0.3$  K lower than the temperature measured with the reference thermometer during the determination of the phase diagram. This systematic temperature shift was taken into account in the following. We assumed the same temperature shift for all microemulsions although the water contents varies slightly between 88.3 vol% (*n*-octane) and 94.3 vol% (*n*-tetradecane).

### 6.3.3. Diffusion Coefficients

The mass diffusion coefficient was directly calculated from the equilibration time,  $\tau_c$ , and the characteristic scattering vector,  $q$ , in the IR-TDFRS setup. Fig.6.8 shows the temperature dependence of the diffusion coefficient for all investigated microemulsion systems close to the *efb*. Starting at the high temperature, the diffusion coefficient first increased with decreasing temperature and finally reached a plateau value below the *efb*.

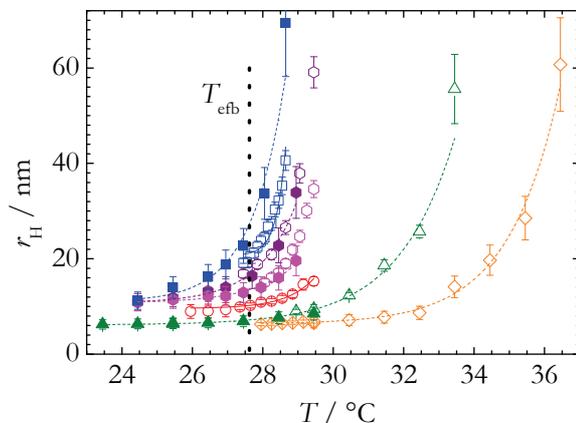

In the plateau below the *efb* the  $1\phi$  phase coexists with an oil excess phase. This plateau

**Figure 6.8.:** The mass diffusion coefficient is plotted versus the temperature in the vicinity of the efb for several microemulsion systems:  $n$ -octane (squares),  $n$ -octane /  $n$ -decane (75/25) (hexagon),  $n$ -octane /  $n$ -decane (50/50) (hexagon),  $n$ -decane (circles),  $n$ -dodecane (triangles up) and  $n$ -tetradecane (diamonds). The black dashed line is a guide to the eyes and marks roughly the efb. Data from IR-TDFRS (open symbols) and from DLS (solid symbols) are compared.

was more pronounced for the long-chained  $n$ -alkane microemulsions, while for the  $n$ -octane system we could not identify a plateau. The same behavior was reflected in the hydrodynamic radius, which was calculated by the Stokes-Einstein-Equation, assuming a spherical shape of the droplets, using the temperature dependent viscosity of pure water. This simplification was justified, since the solubility of  $n$ -alkanes in water is negligible. In Fig.6.9 the temperature dependence of the hydrodynamic radius is shown, which decays with decreasing temperature and reaches a plateau at the  $efb$ .

We obtained the diffusion coefficients and hydrodynamic radii at the  $efb$  by interpolating the measured data in the  $1\phi$  region. It turned out that the temperature dependence of the hydrodynamic radius can be described by a single exponential function, which was used to obtain the hydrodynamic radius at the  $efb$ . We included the data points from the  $2\phi$  region because the phase transition is continuous and spherical droplets are found on both sides of the boundary as it was observed by Corkill *et al.* [353] with NMR measurements in the  $2\phi$  region. In the investigated temperature range, the diffusion coefficients and accordingly the hydrodynamic radius were almost temperature independent. For the long-chained  $n$ -alkane systems, the addition of the  $2\phi$  data points made the result more

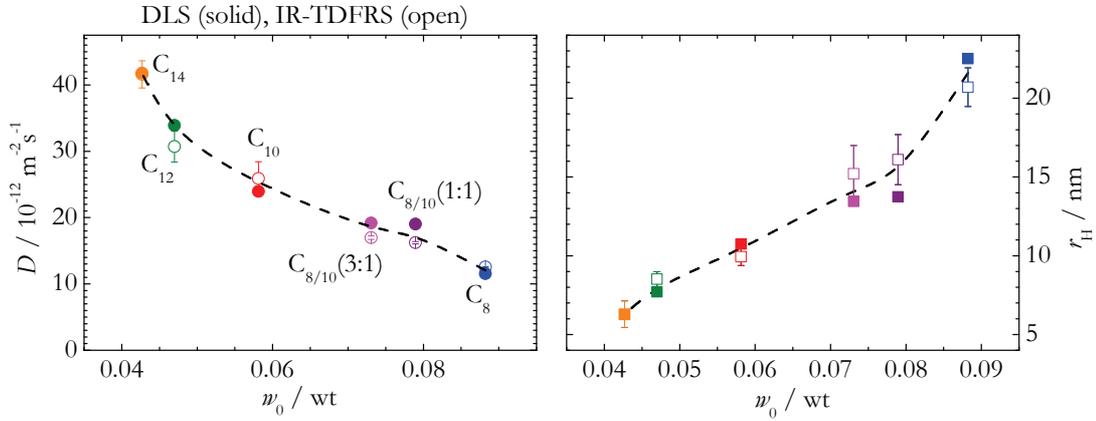

**Figure 6.9.:** The hydrodynamic radius is plotted versus the temperature for several microemulsion systems: n-octane (squares), n-octane / n-decane (75/25) (hexagon), n-octane / n-decane (50/50) (hexagon), n-decane (circles), n-dodecane (triangles up) and n-tetradecane (diamonds). The black dashed line is a guide to the eyes and marks roughly the *efb*.

certain, but did not change the value significantly, which we obtained, if we used only values from the  $1\phi$  region and extrapolated to the *efb*.

#### 6.3.4. Comparison with DLS

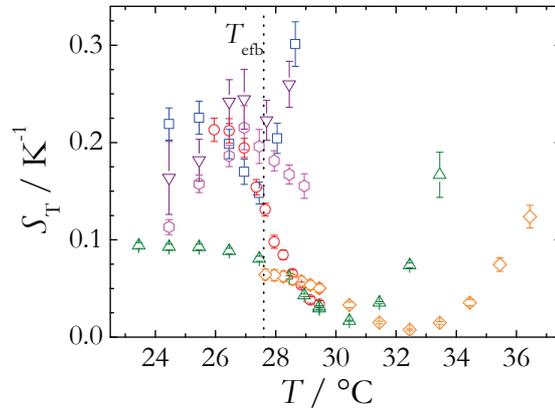

Dynamic light scattering (DLS) experiments were performed within the  $1\phi$  region by the group in Köln. The obtained intensity correlation function  $g_2(t)$  was normalized to one for  $t = 0$  and was analyzed using the Kohlrausch-Williams-Watts function (Eq.3.14) to determine the diffusion coefficient  $D = (\tau q^2)^{-1}$ . The time constant of the diffracted intensity signal in the IR-TDFRS experiment,  $\tau_c$ , is three orders of magnitude smaller than of the DLS setup, because the  $q$ -vector is two orders of magnitude smaller. Fig.6.10 compares the extrapolated diffusion coefficients and the hydrodynamic radii at the *efb* obtained by IR-TDFRS and DLS. In the entire concentration range both setups produce equal diffusion coefficients within the error bars. Usually it is expected that different statistical weights in DLS and TDFRS lead to a slower diffusion in DLS compared to TDFRS experiments, but here we observe also the opposite trend, which is not understood yet.

**Figure 6.10.:** The extrapolated diffusion coefficient (left plot, circles) and hydrodynamic radius (right plot, squares) of all investigated microemulsion systems ( $\gamma_a = 0.03 \text{ wt}$ ) are plotted versus the droplet concentration at the *efb*. Two methods were used to measure  $D$ : the IR-TDFRS (solid symbols) and the DLS setup (open symbols). Symbol colors are used as given in Fig. 6.1. The dashed lines are guides to the eyes.

## 6.4. Calculation of $S_T$ and $D_T$

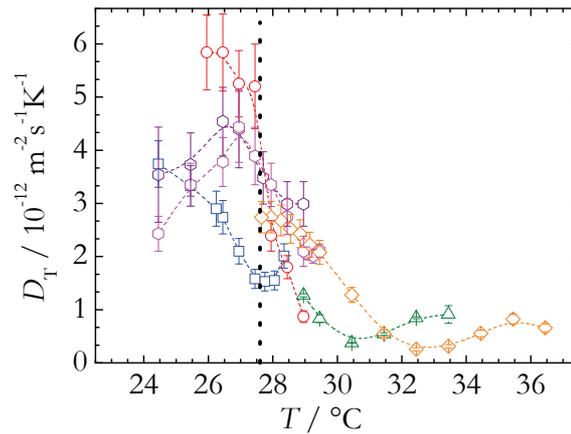

The Soret coefficient, being the ratio of the thermal diffusion coefficient and the mutual diffusion coefficient, was determined within the characteristic  $1\phi$  region in the vicinity of the *efb* for each microemulsion system. Fig.6.11 depicts the temperature dependence of  $S_T$  which is similar for all microemulsion systems: A plateau value was reached for low temperatures just below or in the vicinity of the *efb*, while approaching against the *ncb*,  $S_T$  diverges. In between, a minimum value of  $S_T$  is found. Measurements in the vicinity of the *ncb* were not possible because the diffusion coefficient of the microemulsion structures in the upper part of the  $1\phi$  decays to zero. This characteristic behavior of the Soret coefficient at the *efb* is related to the thermal diffusion coefficient which also shows a plateau at the *efb* (see Fig.6.12). In contrast, near the *ncb* the thermal diffusion coefficient of the microemulsion systems with long-chained *n*-alkanes did not indicate to diverge against the *ncb* as the Soret coefficient did, but relaxed to a rather constant value at  $T = 32.5 \text{ }^\circ\text{C}$  for C<sub>12</sub> and  $T = 36.5 \text{ }^\circ\text{C}$  for C<sub>14</sub>, respectively. This constant behavior of the thermal diffusion coefficient close to a critical point was also found experimentally by Giglio and Vendramini for a aniline-cyclohexane mixture [16]. A theoretical approach is given by Luettmmer-Strathmann [354] who investigated the behavior of  $D_T$  close to phase

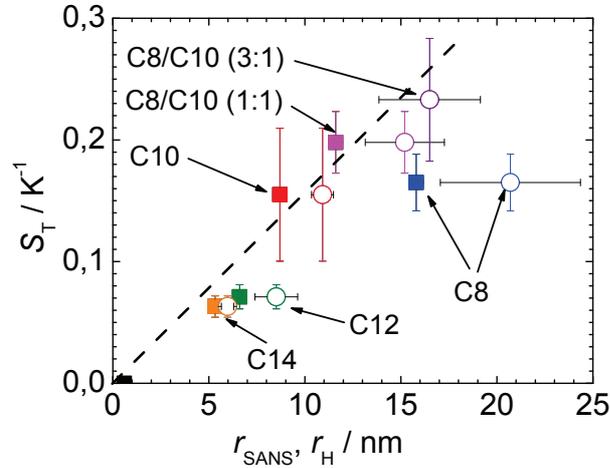

**Figure 6.11.:** The Soret coefficient is plotted versus the temperature. A plateau close to the *efb* (dotted line) is reached. The Soret coefficient diverges towards the *ncb*. Symbols are used as given in Fig. 6.1.

transition boundaries. The typical divergence of  $S_T$  near the *ncb* is then caused by a vanishing mutual diffusion coefficient.

The temperature dependence of the Soret and diffusion coefficients was interpolated to the *efb*. While the temperature dependent behavior of the mass diffusion coefficient could

**Figure 6.12.:** The thermal diffusion coefficient is plotted versus the temperature. A plateau is observed in the vicinity of the *efb*. The vertical dotted line sketches the *efb* schematically. A divergence in the vicinity of the *ncb*, as it was indicated by the Soret coefficient in Fig.6.11, is not indicated. Symbols are used as given in Fig. 6.1.

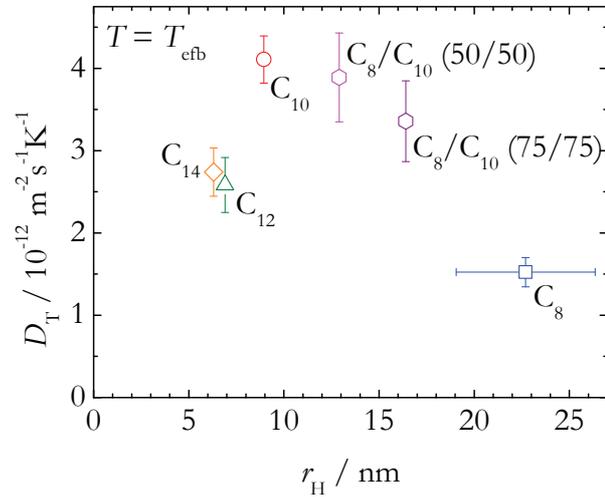

**Figure 6.13.:** The Soret coefficient versus the hydrodynamic radius,  $r_H$ , (open circles) and versus the mean droplet radius determined by SANS measurements,  $r_{SANS}$ , (filled squares) for  $T = T_{efb}$ . Symbol colors are used as given in Fig. 6.1. The dashed line indicates a linear radial dependencies.  $S_T$  and  $r_H$  are interpolated values while the mean droplet radius was measured.

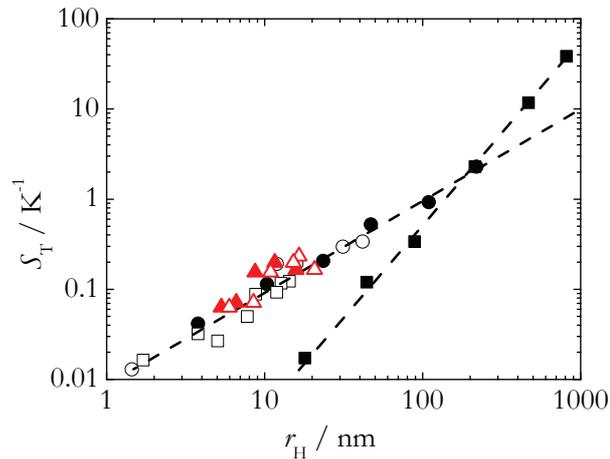

be described by a linear fit above the *efb*, we determined the respective values of the Soret and the thermal diffusion coefficient at the *efb* manually.

In Fig.6.13, the interpolated values of the Soret coefficient are plotted versus the hydrodynamic radius  $r_H$  and versus the mean droplet radius,  $r_{SANS}$ . The mean droplet radius  $r_{SANS}$ , as it was determined by SANS, contains also the width of the surfactant layer, since the measured value of  $r_{SANS}$  approximately corresponds to the distance from the center of the particle to the hydrophilic-hydrophobic intersection of the surfactant in the droplet interface. The values of the hydrodynamic radius were calculated from the diffusion coefficients at the *efb*. Neglecting the *n*-octane system  $S_T$  shows a linear radial dependence. The *n*-octane system turned out to be the most difficult system to be measured due to the narrow temperature range of the  $1\phi$  region.

In Fig.6.15 a comparison of the determined radial dependence of the Soret coefficient with literature results is given. It is clearly shown, that the results of this work coincide with the generally obtained linear radial dependence. Performed SANS measurements showed, that the microemulsion droplets under investigation can be regarded as dynamic solid particles. Thus, the theoretical approach by Würger [339], claiming a linear radial dependence of  $S_T$  for solid particles, is also true for the investigated microemulsion systems.

**Figure 6.14.:** The thermal diffusion coefficient is plotted versus the hydrodynamic radius. Both values are interpolated to the efb. Symbols are used as given in Fig. 6.1.

**Figure 6.15.:** The determined radial dependence of the Soret coefficient is compared with literature results as summarized in [99]. The black symbols refer to following literature results: [65] (filled squares), [66] (filled circles), [35] (open squares), [67] (open circles). The red symbols refer to measurements of this work: TDFRS (filled triangles) and IR-TDFRS measurements (open triangles). Dashed lines are guides to the eyes.

As a consequence of the linear radial  $S_T$  dependence and Eq.2.22, the thermal diffusion coefficient should be independent of the radius. Fig.6.14 shows the radial dependence of  $D_T$ . Both, the radius and the diffusion coefficient, are interpolated to the *efb*. We cannot give a clear radial dependence of  $D_T$  due to large data spreading.

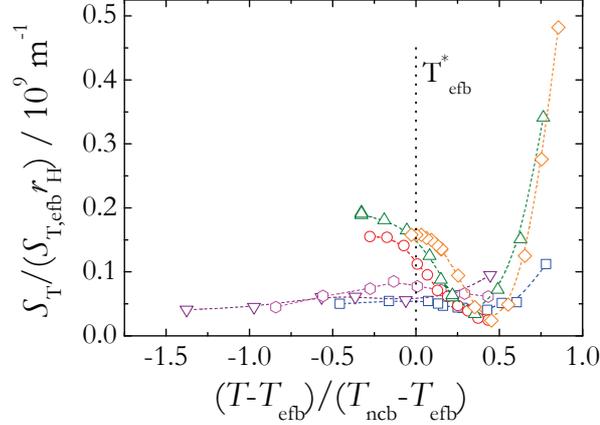

### 6.4.1. Normalization of the Soret Coefficient

Comparing the temperature dependence of the Soret and diffusion coefficients in the  $1\phi$  regions of the investigated *n*-alkane microemulsions, certain similarities were observed, e.g. the divergence of  $S_T$  against the *ncb* or the asymptotical approach towards a plateau close to the *efb* which was found for all systems. For the microemulsion systems under study, this can be explained by the fact that size and structure of the microemulsion droplets in the  $1\phi$  region are defined by the upper and lower phase boundaries and the point, where *efb* and *ncb* meet. Thus, it might be possible to describe the temperature dependence of the Soret coefficient, measured in the  $1\phi$  region of different microemulsions, with a master curve. Therefore, temperature and  $S_T$  need to be normalized. A normalized temperature was introduced which considers the upper and lower  $1\phi$  boundaries. The Soret coefficient was normalized to its corresponding value at the *efb*. The multiplication with the hydrodynamic radius considered the size effect of  $S_T$  with increasing concentration which was determined to be linear. The normalization was:

$$S_T^* = \frac{S_T}{S_{T,efb} \cdot r_H} \quad \text{and} \quad (6.1)$$

$$T^* = \frac{T - T_{efb}}{T_{ncb} - T_{efb}}. \quad (6.2)$$

with the temperatures of the *efb* and *ncb*,  $T_{efb}$  and  $T_{ncb}$ , respectively. The normalized values are denoted with a star. At  $T = T_{efb}$  the reduced temperature is  $T^* = 0$ , while at  $T = T_{ncb}$  it is  $T^* = 1$ . Fig.6.16 shows the normalized Soret coefficient plotted versus the normalized temperature: All microemulsion systems showed a minimum at  $T^* \approx 0.4$  which is close to the temperature in the  $1\phi$  region where some microemulsions containing long-chained *n*-alkanes show a slightly pronounced discontinuity in the temperature dependence of the diffusion behavior. Above this temperature, a diverging behavior against the *ncb* was observed, and below this temperature the asymptotic approach against a plateau close to the *efb* is pictured. We found two different plateau values. The lower plateau was

**Figure 6.16.:** The normalized Soret coefficient versus the normalized temperature. Deviations from a standardized curve are observed for higher concentrated microemulsions. Symbols are used as given in Fig. 6.1.

reached for all microemulsion systems containing *n*-octane, and another higher plateau was found for the systems C<sub>10</sub>, C<sub>12</sub> and C<sub>14</sub>.

## 6.5. Correlation between $S_T$ and the Interfacial Tension

In microemulsion systems, the interfacial tension between the microemulsion droplets and the solvent varies with composition and temperature. Piazza and Parola *et al.* [99] correlate the Soret coefficient with the interfacial tension of the microemulsion droplets. It is stated that the Soret coefficient can be calculated from the derivative of the interfacial tension with temperature as

$$S_T = \frac{4\pi r}{k_B T} \frac{\partial (l_{fluid} \sigma)}{\partial T} \quad (6.3)$$

with the droplet radius,  $r$ , and the length which measures the range of the colloid-solvent interaction,  $l_{fluid}$ . Regarding the microemulsion droplets, we assume that  $r = r_{SANS} + v_c/a_c^2$  and that  $\partial l_{fluid}/\partial T$  is constant. Hence, Eq.6.3 reduces to

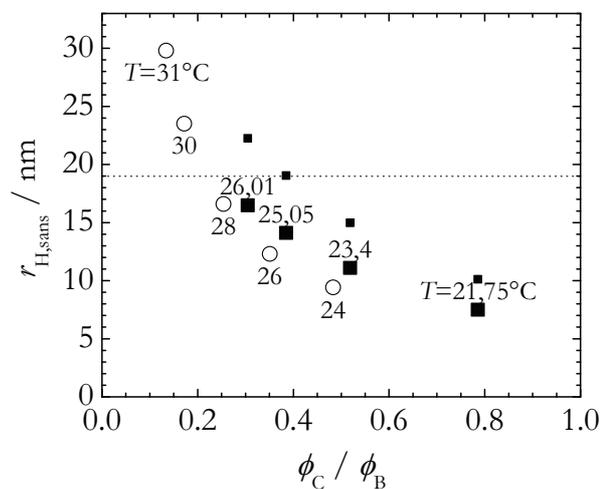

$$S_T = \frac{4\pi r_{SANS} l_{fluid}}{k_B T} \frac{\partial \sigma}{\partial T}. \quad (6.4)$$

In order to apply Eq.6.4 to the microemulsion systems, we use the interfacial tension data of the microemulsion droplets at the *efb* determined by Sottmann [355] (Fig.6.17).

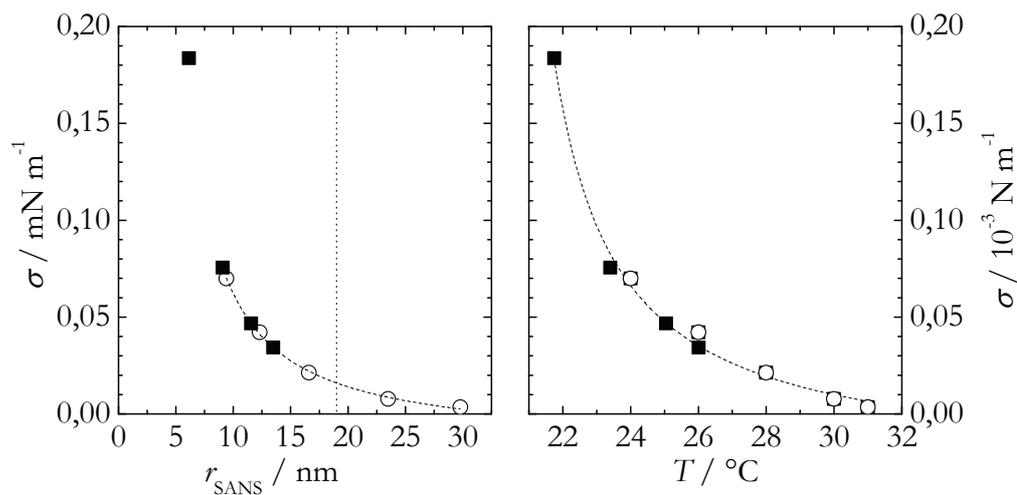

He measured the interfacial tension at different temperatures and concentrations using the spinning-drop technique [247, 356, 357] and also determined the mean radius of the investigated microemulsion droplets by SANS measurements. Thus, if we are able to combine the results from the spinning-drop technique with the results from TDFRS, we can investigate, whether Eq.6.4 describes the dependence of the Soret coefficient as function of the interfacial tension qualitatively. Therefore, we have to prove that both systems, the investigated system in this work and that by Sottmann, are comparable to each other. This is the case if the microemulsion structures in both systems have at least the same curvature at a certain temperature and composition. Assuming spherical droplets in the investigated temperature and concentration range, the curvature is the inverse of the droplet radius. In Fig.6.17 the droplet radius is plotted versus the ratio of the volume fractions of surfactant and oil,  $\phi_C/\phi_B$ . The radius which is given in the work by Sottmann has been determined by SANS, while in this work the radius refers to the hydrodynamic radius determined by IR-TDFRS. As we also determined the radii of some microemulsions by SANS and IR-TDFRS under equal conditions, we use the previously determined factor  $r_H/r_{SANS} = 1.35$  to convert the hydrodynamic radii from IR-TDFRS experiments. Thus, both radii are almost comparable to each other. Fig.6.17 shows that the microemulsion droplets investigated by Sottmann and in this work have equal sizes at equal temperature and ratio of volume fractions.

The surface tension is directly correlated with the principal curvatures ( $c_1, c_2$ ) of the amphiphilic film [358]. For spherical aggregates, it is  $c_1 = c_2 = c$  and hence  $\sigma/c^2 \approx kT$ .

Hence, we take the measured interfacial tension from the data by Sottmann and calculate the temperature derivative of the interfacial tension at certain radii of the microemulsion droplets at the *efb* which are determined by TDFRS measurements in this work. We additionally consider that the hydrodynamic radii determined by TDFRS experiments are by a factor of 1.35 larger than the mean droplet radii,  $r_{SANS}$ , which have to be used instead in Eq. 6.4. For the calculation of  $l_{fluid}$  in Eq. 6.4, also the Soret coefficient of the microemulsion droplets at the *efb* (Fig.6.18) is required and is obtained by TDFRS experiments. Consequently,  $l_{fluid}$  is determined as a function of the *efb* temperature or mean droplet radius at the *efb*, respectively: With increasing temperature,  $l_{fluid}$  increases in absolute values from 0.17 nm at  $T = 21.75$  °C to 5.94 nm at  $T = 28.46$  °C and is thus in the order of the standard deviation of the Gaussian function describing the radius polydispersity around the mean droplet radius of similar microemulsions (see Sec. 6.3). Tab.6.4 lists important parameters which have been used for Eq.6.4.

**Figure 6.17.:** The radius versus the ratio of the volume fractions of surfactant and oil. The numbers close to the data points give the measurement temperatures. Upper numbers refer to the data by Sottmann [355] (open circles) and the lower numbers refer to the data from this work (solid squares). Small symbols represent the hydrodynamic radius, and large symbols give the calculated mean radius to compare with the radii from Sottmann. The dotted line marks the radius, above which the droplet size does not scale linearly with temperature.

The calculated mean radius,  $r_{SANS} = r_H/1.35$ , and the interpolated interfacial tension,  $\sigma$ , are shown.

## 6.6. Preliminary measurements of the w/o-Droplets

In the previous sections, the Soret coefficient of o/w-microemulsion droplets in the  $1\phi$  region on the water-rich side of the phase diagram has been investigated. For these systems, a linear radial dependence of  $S_T$  was found. The main question is, if also the Soret coefficient of w/o-droplets shows a linear radial dependence. These discrete w/o-droplets are formed in a  $1\phi$  region at the oil-rich side of the phase diagram [359–361] and can be treated as reverse micelles of a monolayer surfactant film which separates water from oil [362]. The inner core is formed by water and the hydrophilic surfactant head group. The hydrophobic surfactant chain is in contact with the surrounding oil phase. One discriminates between a water core, which is impenetrable for the oil, and a flexible penetrable shell. The maximum thickness of the shell is given by the extended length of the surfactant chain and increases with temperature [363]. A sticky hard sphere potential can be assigned to the w/o-droplet for which the flexible layer thickness is regarded as the stickiness parameter of the short-ranged attractive potential [363–365]. A comparison with o/w-droplets shows that attractive interactions between w/o-droplets are less pronounced than attractive interactions between o/w-droplets [366].

We investigated microemulsion droplets in the  $1\phi$  funnel on the oil-rich side of the  $\text{H}_2\text{O}/\text{C}_8/\text{C}_{12}\text{E}_5$  phase diagram. The oil-to-surfactant ratio was constant at  $\gamma_b = 0.04$  wt and the water mass fraction  $w_A$  has been varied between 0.02 wt and 0.05 wt. The corresponding  $1\phi$ -funnel has been measured in Köln and is shown in the left plot of Fig.6.19. The *efb* is the upper phase boundary and the *ncb* is the lower one. All thermal diffusion measurements (here not shown in detail) have been performed in the  $1\phi$  region. As the measurement directly at the *efb* was not possible, we performed the measurements at different temperatures below the *efb* and extrapolated the Soret coefficient and the hydrodynamic radius to the *efb*. We had to measure carefully because the funnel temperature is approximately 20 °C above room temperature which causes the risk of phase transitions during or even before the measurements. The main problem is, that the microemulsions which have been filled in the thin flow cells in a thermostated environment, cooled down within a few seconds to room temperature while the cells are transferred to the thermostated cell holder of the classical TDFRS setup.

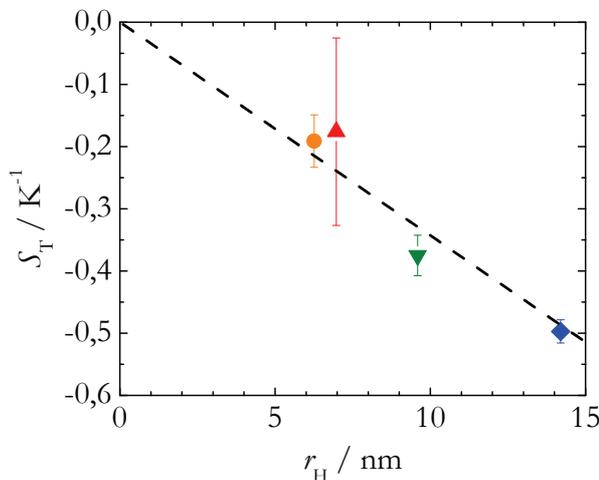

The hydrodynamic radius was determined from classical TDFRS measurements with the assumption of spherical droplets at the *efb*. We also assumed that the viscosity of the solvent is approximately equal to the viscosity of the pure *n*-octane because the solubility of water in *n*-octane is low and the surfactant assembles in the oil-water interface. In

**Figure 6.19.:** *Left:* Phase diagram of the  $1\phi$  funnel on the oil-rich side with the efb (squares) and the ncb (circles). *Right:* The hydrodynamic radius versus the water concentration,  $w_A$ . Mass fractions:  $w_A = 0.02 \text{ wt}$  (circles),  $w_A = 0.03 \text{ wt}$  (triangles up),  $w_A = 0.04 \text{ wt}$  (triangles down) and  $w_A = 0.05 \text{ wt}$  (diamonds). The dashed line is a linear fit. *Inset:* The Soret coefficient of  $\text{H}_2\text{O}/\text{C}_8/\text{C}_{12}\text{E}_5$  at the efb versus the water concentration at constant  $\gamma_b = 0.04 \text{ wt}$ .

the inset in the right plot of Fig.6.19 the extrapolated Soret coefficient versus the water concentration is shown.  $S_T$  is negative and decreases linearly with increasing water concentration. Nevertheless, the w/o-droplets move to the cold. This unexpected combination of a negative Soret coefficient and the motion to the cold is caused by the negative contrast factor  $(\partial n / \partial w)_{p,T}$  as the increase in the water content of the solution will lower the main refractive index.

The plot of the Soret coefficient versus the hydrodynamic radius shows an almost linear radial dependence in the investigated concentration range (see Fig.6.20). The investigation of larger droplets, as they are formed in microemulsions with higher water contents, was not possible because the  $1\phi$  funnel becomes narrower in temperature at higher water contents.

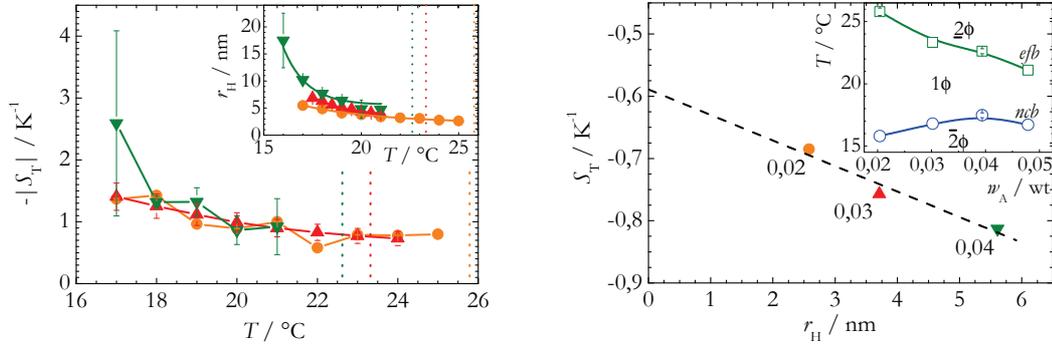

**Figure 6.20.:** The Soret coefficient versus the hydrodynamic radius at the *efb* at constant  $\gamma_b = 0.04$  wt for *w/o*-droplets of the  $H_2O/C_8/C_{12}E_5$  microemulsion. Symbols are used as given in Fig. 6.19.

### 6.6.1. *w/o*-Droplets of a quaternary Microemulsion

Most of the problems during the measurements in the  $1\phi$  region on the oil-rich side of the  $H_2O/C_8/C_{12}E_5$  phase diagram stem from the fairly high *efb* temperatures between  $38.5\text{ }^\circ\text{C}$  ( $w_A = 0.05$  wt) and  $43.3\text{ }^\circ\text{C}$  ( $w_A = 0.02$  wt). To overcome these temperature problems, an approach is to add a fourth component glycerol, which affects the phase boundaries [367] by lowering the cloud point [368]. Also the main temperature of the  $1\phi$  region is lowered. The hydrophilic glycerol goes into the water phase and a glycerol-to-water ratio of 0.35 wt/0.65 wt was selected which decreases the temperatures of the *efb* to  $21\text{ }^\circ\text{C}$  ( $w_A = 0.05$  wt) and  $26\text{ }^\circ\text{C}$  ( $w_A = 0.02$  wt). The phase diagram is given in the inset on the right side of Fig.6.21. Thermal diffusion measurements have been performed in the  $1\phi$  region and the data have been extrapolated to the *efb* using an exponential function. The Soret coefficient and the hydrodynamic radius approach a plateau value close to the *efb* (for both plots see left Fig.6.21).

Finally, the right Fig.6.21 shows a linear size dependence of the Soret coefficient. Differences to the *w/o*-droplets of the glycerol-free microemulsions are the larger absolute values of the Soret coefficient by a factor of two, and the droplet sizes which are almost halved for each concentration. The different droplet sizes can be explained as follows: Glycerol might cause dehydration of the hydrophilic head groups of the surfactant because it is

**Figure 6.21.:** *Left:* The absolute value of  $S_T$  versus temperature. The mass fractions are:  $w_A = 0.02$  wt (circles),  $w_A = 0.03$  wt (triangles up) and  $w_A = 0.04$  wt (triangles down). Vertical lines mark the emulsification failure boundaries. Inset: The corresponding hydrodynamic radius versus temperature. *Right:* The Soret coefficient at the *efb* versus the hydrodynamic radius in the  $\text{H}_2\text{O}/\text{glycerol}/\text{C}_8/\text{C}_{12}\text{E}_5$  microemulsion at constant  $\gamma_b = 0.04$  wt. Symbols are used as given in Fig. 6.19. The dashed line is a linear fit. Inset: The phase diagram.

a less effective solvent than water. So, glycerol will not preferentially interact with the surfactant head group units but competes with them for water molecules. This causes a dehydration of the hydrophilic surfactant units which in turn causes an increase in the interactions between the surfactant head groups and leads to a contraction of the inner droplet core surface. The micelle shrinks [368, 369].

## 6.6.2. Conclusion

These preliminary measurements on the oil-rich side of the phase diagram of  $\text{H}_2\text{O}/\text{C}_8/\text{C}_{12}\text{E}_5$  and  $\text{H}_2\text{O}/\text{glycerol}/\text{C}_8/\text{C}_{12}\text{E}_5$  have been performed to investigate the thermal diffusion properties of the w/o-droplets. It was shown that the Soret coefficient is negative and approaches a constant value at the *efb*.  $S_T$  and the hydrodynamic radius at the *efb* scale almost linearly with the water concentration. A linear radial dependence of the Soret coefficient was found. The addition of glycerol decreased the funnel temperatures which in turn lowered the risk of phase transitions during the measurements. Also for the glycerol system a linear radial dependence of  $S_T$  has been observed. But there are still open questions to be answered. To our best knowledge, we assumed spherical droplets at the *efb*, but this has to be investigated, e.g. by SANS measurements. Furthermore, the determined droplet radii do not only include a small layer of *n*-octane molecules.

Additionally, also a layer of dissolved surfactant molecules is included, which spatial distribution is not homogeneous but shows a higher probability for find the surfactants close to the droplet [370].

It is also unclear to which extend the flexible interface of the w/o-droplets influences the thermal diffusion behavior for different droplet sizes. In the case that the interface can be regarded as a soft interface, Würger [68] predicts a quadratic radial dependence of  $S_T$ . But this cannot be confirmed by our findings.

Another point is the temperature influence on the thermal diffusion behavior of the w/o-droplets at the *efb*. This influence was pronounced in the water-rich  $1\phi$  funnel of  $H_2O/C_8/C_{12}E_5$ , so that the linear radial dependence of  $S_T$  turned into a quadratic dependence. For the w/o-droplets, the Soret coefficient depends linearly on the droplet radius even if the variation of the water concentration changed the *efb*-temperature. In future projects, we have to determine the Soret coefficient of different droplet radii without changing the *efb* temperature to identify the temperature influence.

## CONCLUSION

The goal of this thesis was twofold: First we studied the thermal diffusion behavior below and above the critical micelle concentration (*cmc*) of micellar solutions. Second the size dependence of the Soret coefficient by means of microemulsions as model systems has been investigated.

In the first part of this work, the micellar systems were investigated. To our best knowledge, the thermal diffusion behavior of a micellar system around the critical micelle concentration has not been systematically investigated before. This work was motivated by a thermal lens study by Santos *et al.* [34]. They found an abrupt change of the thermal lens signal at the *cmc*. Unfortunately, they were not able to determine the Soret coefficient due to the presence of dye. In this work, the surfactant *n*-Octyl  $\beta$ -D-glucopyranoside, which has a fairly high *cmc*, was used for comprehensive measurements of the thermal diffusion properties in the low concentration regime close to the *cmc*. We used IR-TDFRS, which uses a weak absorption band of water in the near infrared and works without dye. The *cmc* was determined by surface tension measurements. It was found that the Soret coefficient is almost temperature- and concentration-independent in the concentration regime below the *cmc*, while above the *cmc*, micelles influence the thermal and mass diffusion coefficients. Unfortunately, it was not possible to separate micellar diffusion from molecular diffusion, as the time constants are too close to each other to resolve with IR-TDFRS. To tie in with the work of Santos *et al.*, we performed measurements with classical TDFRS, which also works with an absorbing dye. Using classical TDFRS we could show that an ionic dye influences the thermal diffusion behavior above the *cmc* only if the dye

absorbs at the wavelength of the writing laser. A comparison of the different studies with and without dye in both forms of TDFRS showed that the abrupt change in the thermal coefficients also gets enhanced under this conditions.

In the higher concentration regime, corresponding to approximately the twice the *cmc*, where the diffusion is dominated by micelles, the hydrodynamic radius of  $C_8G_1$  micelles determined by TDFRS is equal to the calculated length of the surfactant molecule. It was determined that the Soret coefficient undergoes a sign inversion from positive to negative with increasing concentration. Additionally, a temperature dependence of the sign inversion has been observed.

To check if the concentration and temperature dependencies of the Soret coefficient, determined for the  $C_8G_1/H_2O$  system, are general features of this class of sugar surfactants, the measurements were extended to  $C_7G_1/H_2O$  and  $C_8G_2/H_2O$ . Preliminary measurements of the critical micelle concentrations indicated a *cmc* three times higher of  $C_7G_1$  than that of  $C_8G_1$  due to a reduced hydrophobic chain length. Due to impurities in both batches of  $C_8G_2$  a reliable determination of the *cmc* with the ring method was not possible. In contrast, the TDFRS results showed also for  $C_8G_2$  a pronounced change of  $S_T$  at a concentration which is in the same order as the literature value for the *cmc*. This indicates that the micelle formation in the bulk is less influenced by impurities. All investigated systems showed a sign inversion at higher concentrations. Some approaches have been introduced to normalize the Soret coefficient as function of temperature for all investigated solutions.

The second part of this work focused on the investigation of microemulsion systems. Microemulsions were used as model systems of spherical particles to determine the radial dependence of the Soret coefficient, which is controversially discussed in the literature. Whether the Soret coefficient scales linearly or quadratically with the radius, was investigated. In contrast to recently published works using synthesized colloidal particles or ionic microemulsion droplets, the approach of this work employs the same chemical surface composition for all sizes and eliminates surface charge effects. The size of the droplets under investigation is in the range 6.3 nm (*n*-tetradecane) to 19.7 nm (*n*-octane) and is small enough to ensure that sedimentation does not occur.

Microemulsion droplets can be found in the  $1\phi$  region. A microemulsion of type  $H_2O/C_8/C_{12}E_5$  was selected for study because the  $1\phi$  region is experimentally accessible close to room temperature. The  $1\phi$  region on the water-rich side of the phase diagram, surrounded by the emulsification failure boundary (*efb*) to the lower  $2\phi$  region and by the near critical boundary (*ncb*) to the upper  $\bar{2}\phi$  region, is called  $1\phi$ -*funnel*. In this funnel

---

o/w-droplets are found. These droplets have a spherical shape at the *efb* and grow in size with increasing *n*-octane concentration. An increase in temperature leads to ellipsoidal or network-like structures close to the *ncb*. The phase diagram of the  $1\phi$  funnel was determined within which thermal diffusion measurements were performed. To calculate the Soret coefficient, the refractive index increment with temperature is required. As some microemulsions are turbid, an optimized Michelson interferometer was constructed.

Because of possible phase transitions at the *efb* from  $1\phi$  to  $2\phi$  during the TDFRS measurements, the samples could not be measured at the *efb*. Instead, temperature series were performed in the  $1\phi$  approaching the *efb*, and the Soret and diffusion coefficients were extrapolated to the *efb*. The temperature dependence of the Soret coefficient, at constant composition, approaches a constant value at the *efb*, while  $S_T$  diverges in the vicinity of the *ncb*. A variation of the *n*-octane concentration results in a size variation of the droplets. The determination of the Soret coefficient along the *efb* yields the radial dependence. For  $\text{H}_2\text{O}/\text{C}_8/\text{C}_{12}\text{E}_5$ , a linear radial dependence was determined, but the measurements for the different droplet sizes were not performed at the same temperature. It therefore remains unclear whether the result was additionally influenced by temperature changes.

To measure the Soret coefficient of o/w-droplets under isothermal conditions at the *efb*, microemulsion systems, which consisted of different *n*-alkanes, were produced. An increase of the *n*-alkane chain length shifts the  $1\phi$  region towards higher temperatures and towards lower mass fractions of the *n*-alkane. It is therefore possible that each  $\text{H}_2\text{O}/\text{C}_x/\text{C}_{12}\text{E}_5$  microemulsion shows the *efb* at the same temperature, but with a different droplet size and different *n*-alkane concentrations. The shortest investigated *n*-alkane is *n*-octane, which exhibits a temperature difference of 2 K between the *efb* and the *ncb* at the investigated concentration. The measurement of a shorter *n*-alkane such as *n*-hexane is experimentally difficult, due to an even narrower funnel and a high evaporation rate. The longest *n*-alkane investigated was *n*-tetradecane, due to solubility problems for longer alkane chains. Thus, *n*-alkanes with an even number of carbon units from 8 to 14 were studied. *N*-alkanes with an odd number of carbon units were not considered as they show slightly different physical properties which makes them unsuitable. The investigated samples varied in their droplet volume fraction from 4.75 vol% (*n*-tetradecane) to 11.15 vol% (*n*-octane), and in the droplet hydrodynamic radius from 6.3 nm (*n*-tetradecane) to 19.7 nm (*n*-octane). For all *n*-alkane systems, small angle neutron scattering experiments were performed to confirm the spherical shape at the *efb* and to determine the droplet-droplet interactions. A combination of a sticky hard sphere structure factor and a core-shell form factor was

used to describe the data. As expected, it was found that the interactions are more pronounced at higher droplet volume fractions. Analyzing the Soret coefficient of these different microemulsion systems leads to a linear dependence of the Soret coefficient with droplet size.

An approach by Parola and Piazza [371] gives evidence that the Soret coefficient correlates with the radius of the solute particle, and with the temperature derivative of the product of the particle-solvent interfacial tension and the length which measures the range of the colloid-solvent interaction,  $\partial(l_{fluid}\sigma)/\partial T$ . It is assumed that  $S_T$  scales linearly with the particle radius and with  $\partial\sigma/\partial T$ . The main question was if the width of the fluid layer could be related to the thickness of the diffuse interface of the microemulsion droplets,  $t_{di}$ . The interfacial tension of a  $H_2O/C_8/C_{12}E_5$  microemulsion determined by Sottmann was compared with thermal diffusion and SANS measurements. It was found that the thickness parameter of the diffuse interface of the sticky hard sphere potential and the width of the fluid layer are both in the order of a nanometer.

## 7.1. Outlook

Future projects will be focused on microemulsion systems. In this work, the radial dependence of the Soret coefficient was determined at constant temperature. This system can also be used to investigate the dependence of the droplet density on the Soret coefficient at constant droplet radius and temperature. This allows a systematic study to be made of the thermal diffusion behavior of single-particle and particle-particle interactions, which can be compared with existing theories for colloids. For these measurements, microemulsion systems that have already been characterized, like  $H_2O/C_{10}/C_{12}E_5$ , can be used. A variation in the droplet density can be achieved by changing the surfactant-to-water ratio,  $\gamma_a$ , and the  $n$ -alkane concentration,  $w_B$ . Thereby, the *efb*-temperature and the droplet size both are unattached. First measurements of the refractive index increments indicate that the  $1\phi$  funnel temperatures of these systems are in an experimentally accessible range so that we are able to measure these systems carefully using IR-TDFRS.

On the oil-rich side of the phase diagram of the investigated system  $H_2O/C_8/C_{12}E_5$  w/o-droplets are formed. They behave like inverse micelles. The investigation of the thermal diffusion behavior of the w/o-droplet was difficult, due to the high temperatures of the gap between the *efb* and the *ncb* which lays between 35 °C and 43 °C. To lower the temperature regime of the funnel, glycerol can be added. First measurements of this quaternary

system are promising and a Soret coefficient has been determined which depends linearly on the radius. But there are still open questions: An alkane soluble dye, Quinizarin, has been added to convert the intensity grating into a thermal grating. The role of the dye on the thermal diffusion behavior has to be identified. SANS measurements are required to determine how far the dye is incorporated in the microemulsion droplets and to get information about the droplet size and shape, especially if glycerol is added.

Regarding the sample holders in TDFRS, they can be replaced by thermostated toluene baths. Toluene has almost the same refractive index as the quartz glass windows of the sample cells. This reduces perturbing scattering close to the measuring volume. Also the thermal stability of the sample during the measurement will be improved.

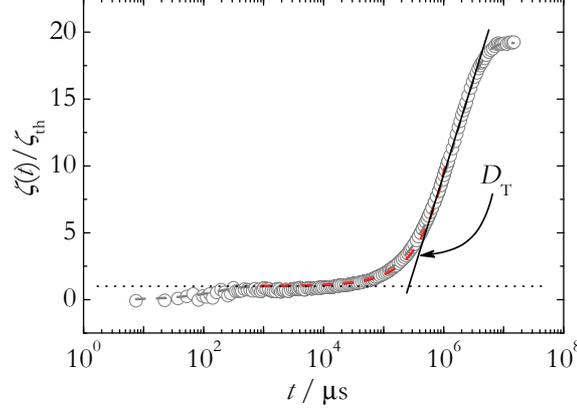

## TAYLOR EXPANSION OF THE HETERODYNE DIFFRACTION SIGNAL

In general the obtained time dependent intensity function from TDFRS experiments was analyzed using Eq.3.8 to determine the Soret and diffusion coefficients. Sometimes the analysis of the diffraction signal became difficult, for instance if the thermal plateau was less apparent due to a pronounced amplitude of the concentration plateau. This case was often observed for microemulsion systems at temperatures close to the near critical boundary, near which the amplitude of the diffraction signal diverged. Fig.A.1 shows an example for a H<sub>2</sub>O/C<sub>8/10</sub> (75/25)/C<sub>12</sub>E<sub>5</sub> ( $\gamma_a = 0.03$  wt,  $w_B = 0.0505$  wt,  $T = 29.05$  °C), where the thermal plateau was rather small, so that the standard fit procedure failed. Instead, a partial analysis of the measurement signal was used. Here, a Taylor expansion was used to analyze the slope of the concentration process to determine  $D_T$  which is the slope of that function.

The concentration process of the normalized heterodyne intensity signal is

$$\zeta_{\text{het}}(t) = A \left[ 1 - w_0 \frac{D_T}{D} \frac{\left(\frac{\partial n}{\partial T}\right)_{p,w}}{\left(\frac{\partial n}{\partial w}\right)_{p,T}} \left(1 - e^{-\frac{t}{\tau_c}}\right) \right] \quad (\text{A.1})$$

with the heterodyne intensity signal,  $\zeta_{\text{het}}$ , the amplitude of the signal,  $A$ , the diffusion coefficients,  $D_T$  and  $D$ , the process time for the concentration mode,  $\tau_c$  and the derivatives of the refractive index by temperature,  $(\partial n/\partial T)_{p,w}$ , and by concentration,  $(\partial n/\partial w)_{p,T}$ ,

**Figure A.1.:** The normalized heterodyne intensity signal versus time (circles). The dashed line represents the Taylor function. Data points which were used to fit Taylor are colored black, others grey. Dotted lines are guides to the eyes. The time scale is logarithmic. The mean square deviation of the fit is less than 1 %. Sample:  $H_2O/C_{8/10}$  (75/25)/ $C_{12}E_5$ ,  $\gamma_a = 0.03$  wt,  $w_B = 0.0505$  wt,  $T = 29.05$  °C.

respectively.  $w_0$  is the mass ratio of the microemulsion droplets to the total mass. We shorten the expression in Eq.A.1 to

$$\zeta_{\text{het}}(t) = C_1 \left[ 1 - C_2 \left( 1 - e^{-\frac{t}{\tau_c}} \right) \right] \quad (\text{A.2})$$

and insert  $C_1$  and  $C_2$  as coefficients for the following comparison with a polynomial Taylor function  $P(t)$

$$P(t) = p_0 + p_1 t + p_2 t^2 + p_3 t^3 + \dots \quad (\text{A.3})$$

where  $p_i t^i$  are the polynomial terms of the  $i^{\text{th}}$ -order. The approximation of  $\zeta_{\text{het}}$  by Taylor expansion follows the sum of terms of the derivative functions at the single point  $a = 0$

$$P_\zeta(t) = \sum_{n=0}^{\infty} \frac{\zeta_{\text{het}}^{(n)}(a)}{n!} (t - a)^n \quad (\text{A.4})$$

which is expanded to the first order and given by

$$P_\zeta(t) = C_1 - C_1 C_2 \frac{t}{\tau_c} \quad (\text{A.5})$$

The process time  $\tau_c$  will later cancel with a term included in  $C_2$  as  $C_2 \sim \tau_c^{-1}$ . If terms of higher orders were considered, the process time would remain as an additional parameter.

The Taylor function was also expanded to the second order term (not shown here) but it was indicated that the accuracy was not enhanced. Thus, the comparison of the first to terms in Eqs.A.3 and A.5 give the relations

$$p_0 = C_1 = A \text{ and} \quad (\text{A.6})$$

$$p_1 = -C_1 C_2 \frac{1}{\tau_c} = -A c_0 \frac{D_T}{D} \frac{\left(\frac{\partial n}{\partial T}\right)_{p,w}}{\left(\frac{\partial n}{\partial w}\right)_{p,T}} \frac{1}{\tau_c}. \quad (\text{A.7})$$

with the ratio of both Taylor parameters

$$\frac{p_1}{p_0} = -c_0 q^2 D_T \frac{\left(\frac{\partial n}{\partial T}\right)_{p,w}}{\left(\frac{\partial n}{\partial w}\right)_{p,T}} \quad (\text{A.8})$$

where the relation for the mass diffusion coefficient  $D = (q^2 \tau_c)^{-1}$  with the wave vector  $q$  is used. Finally, an expression for  $D_T$  was achieved which is independent of the concentration process time,  $\tau_c$ , and the amplitude,  $A$ . The Taylor expression for  $D_T$  is

$$D_T = -\frac{p_1}{p_0} \cdot \frac{1}{q^2 c_0} \frac{\left(\frac{\partial n}{\partial T}\right)_{p,w}}{\left(\frac{\partial n}{\partial w}\right)_{p,T}}. \quad (\text{A.9})$$

Fig.A.1 shows the heterodyne intensity signal versus time. The dashed black line is the Taylor function from Eq.A.5. The wave vector in the IR-TDFRS setup was determined to  $q = 306010 \text{ m}^{-1}$ , and the increment of the refractive index with concentration and temperature,  $(\partial n / \partial w)_{p,T} = 0.13 \text{ wt}^{-1}$  and  $(\partial n / \partial T)_{p,w} = 5.24 \cdot 10^{-5} \text{ T}^{-1}$ , were determined in separate experiments.

---

## INFLUENCE OF DYE ON MICROEMULSION SYSTEMS IN THE TDFRS SETUPS

---

The effect of ionic dye in a nonionic surfactant solution on the thermal diffusion behavior was discussed in Chapter 4. For a binary micellar solution it was shown that the dye only influenced the micellar concentration regime above the *cmc*. This effect was enhanced if the dye absorbed at the writing laser wavelength. The question emerged if this behavior could also be observed for o/w-microemulsion droplets.

First measurements of o/w-microemulsion droplets were performed for H<sub>2</sub>O/C<sub>8</sub>/C<sub>12</sub>E<sub>5</sub> systems using the classical- and the IR-TDFRS setup, respectively. Basantol<sup>®</sup> Yellow was added to the microemulsion system to achieve an optical density of 2.0 cm<sup>-1</sup> at 488 nm (which is equal to a volume fraction of  $1.504 \cdot 10^{-7}$  mol/g Basantol<sup>®</sup> Yellow). In IR-TDFRS the samples were measured with and without dye.

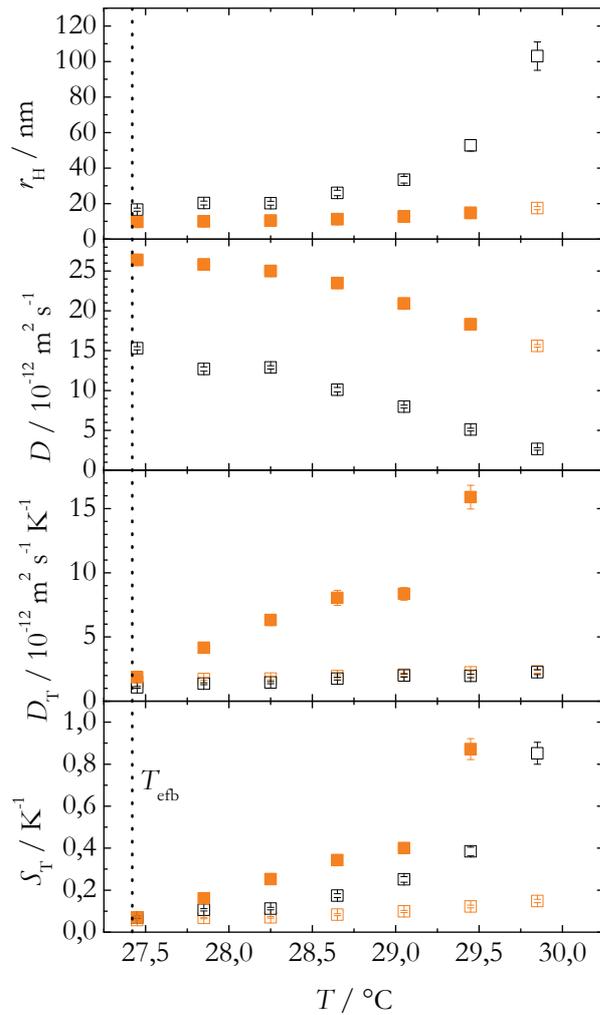

It is expected that the ionic dye molecules are dissolved in water or attached to the surfactant layer of the droplet [39] where they are known to affect the molecular diffusion due to electrostatic interactions. We investigated the dye influence using a H<sub>2</sub>O/C<sub>8</sub>/10 (75/25)/C<sub>12</sub>E<sub>5</sub> microemulsion with  $\gamma_a = 0.03$  wt and  $w_B = 0.0505$  wt. All measurements were performed in the  $1\phi$  region which showed the *efb* approximately at  $T = 27.40$  °C. The starting temperature was 29.85 °C and after each measurement, the temperature was decreased by 0.40 K until the *efb* temperature was reached.

Fig.B.1 shows the determined Soret and diffusion coefficients and the hydrodynamic radius versus temperature. The top figure presents the hydrodynamic radius. The exponential

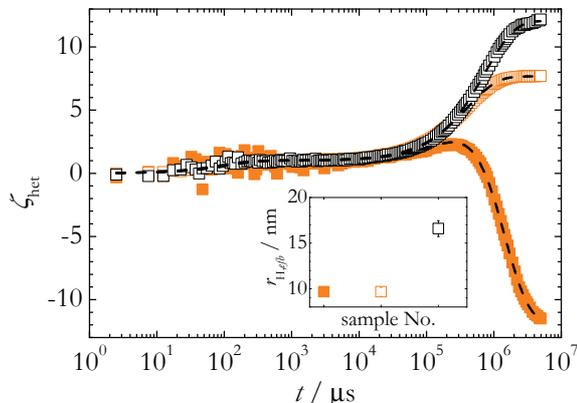

decay of the radius with decreasing temperature is indicated for the dye-free microemulsion. Comparing the results obtained by IR-TDFRS, it is assumed that the dye-containing sample consist of smaller droplets which are 2–10 times smaller than the aggregates of the dye-free sample. This difference is constant over a relatively large temperature range close to the *efb* and becomes larger above 29 °C. We assumed, that this is the critical temperature where the dye-free microemulsion changed shape. In contrast, this is hindered by the influence of the dye. The droplet size diverged stronger against the *ncb* in the absence of dye. Thus, it is predicted, that the ionic influence of the dye hindered the formation of aggregates above 20 nm in radius due to electrostatic repulsion. This behavior was also observed for the dye-containing sample in the classical TDFRS setup. In the classical setup, the dye absorbs on the wavelength of the writing laser which influenced the thermal diffusion behavior of the droplets: The thermal diffusion coefficient determined in IR-TDFRS is equal and almost temperature independent for the dye-containing and dye-free sample but in the classical setup,  $D_T$  increased linearly with temperature.

Consequently the Soret coefficient behaved as follows:  $S_T$  increased with temperature and diverged against the *ncb* for the dye-containing microemulsion in classical TDFRS and the dye-free microemulsion in IR-TDFRS. The increase was less pronounced for the dye-containing sample in IR-TDFRS. In the investigated temperature range, the Soret coefficient was the largest for the microemulsion measured in classical TDFRS, followed by the dye-free sample in IR-TDFRS and  $S_T$  was the smallest for the dye-containing sample in IR-TDFRS. At the *efb* the Soret coefficient was equal for all measurements.

The discrepancy in the classical setup is a matter of the laser wavelength. In this setup a second concentration process was induced due to the local heating of the dye-infected microemulsion droplets. A similar behavior was observed for nonionic micelles in water by Ning *et al.* [38, 39]. After the temperature profile was created, the microemulsion aggregates moved to the cold region, which led to a further increase in the heterodyne intensity signal. Then, induced by a local temperature profile around dye-infected droplets, the dye-infected droplets migrated to the warm. Assuming that the warm region is colder than the local temperature around the dye-infected droplets, this motion can be interpreted as a migration to the cold from the point of view of a droplet. This second concentration process caused a loss in the contrast of the refractive index profile and the diffraction signal decreased. After approximately 10 s a steady state was reached (see Fig.B.2). Fig.B.2 also indicates, that the change in the refractive index grating caused by the concentration process was more pronounced in the IR-TDFRS in the absence of dye which directly correlates to the difference in hydrodynamic radius (inset in Fig.B.2).

**Figure B.1.:** From top to bottom: The temperature dependence of  $r_{\text{H}}$ ,  $D$ ,  $D_{\text{T}}$  and  $S_{\text{T}}$  for the microemulsion system  $\text{H}_2\text{O}/\text{C}_{8,10}$  (75/25)/ $\text{C}_{12}\text{E}_5$  with  $\gamma_{\text{a}} = 0.03$  wt and  $w_{\text{B}} = 0.0505$  wt. The vertical dotted line marks the efb. Symbols are filled (classical TDFRS) or open (IR-TDFRS). Sample with dye (orange) and without dye (black) were investigated.

**Figure B.2.:** Comparison of TFDRS measurements of the same microemulsion system  $H_2O/C_{8,10}/C_{12}E_5$  with  $\gamma_a = 0.03$  wt and  $w_B = 0.0505$  wt at  $T = 27.4$  °C. Symbols are filled (classical TDFRS) or open (IR-TDFRS) and the orange color indicates dye-containing samples while the black symbols represent measurements of dye-free samples. The sample in the classical TDFRS setup shows a second concentration mode while the samples in the IR-TDFRS setup indicate a single concentration plateau. Inset: the hydrodynamic radius at the efb of the dye-free sample is nearly twice of the radius of the dye-containing samples.

The measurements from the classical TDFRS setup indicated a second concentration mode which made the analysis more difficult. To simplify the analysis, the calculated diffusivity, the process time and the amplitude of the single concentration process from IR-TDFRS measurements had been copied as initial values for the triple exponential function, which was used to analyze the classical TDFRS data, which requires two additional parameters: the amplitude and the equilibration time of the second concentration process. The fit procedure was repeated for several times. In each single repetition only an arbitrary pair of the five available parameters was set variable such that after innumerable number of repetitions, the fit function showed a sufficient correlation to the data points.

Contrarily to the o/w-aggregates, the w/o-aggregates were measured in the classical TDFRS (and only there) by adding Quinizarin. The results (not shown here) did not show a second concentration mode. This indicated that the second mode effect was caused by charged molecules acting like a cosurfactant [38].

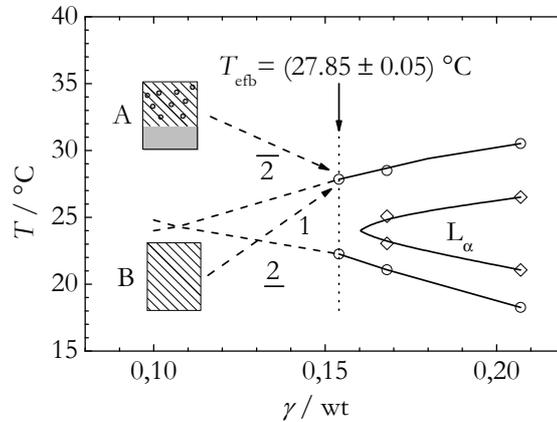

---

## DETERMINATION OF THE TEMPERATURE OFFSET IN THE IR-TDFRS SETUP

---

Two interfering laser beams at 980 nm are used in the IR-TDFRS setup to write a thermal grating into the sample. The low absorption of water is used to convert the intensity grating into a temperature grating. It is suggested that the aqueous samples are locally heated by the laser. This heating cannot be detected by the temperature sensor underneath the sample position in the cell holder. The main problem is that microemulsions depend strongly on temperature and a small temperature variation can cause a phase transition. Thus, we have to ensure to which extend the samples are heated by the IR-laser. First remarks were made by Köhler and Rossmannith [24]. They calculated the additional sample heating based on the thermal conductivity ( $1.4 \cdot 10^{-1} \text{ J cm}^{-1} \text{ s}^{-1} \text{ K}^{-1}$ ) and the thickness of the used cell window (1.25 mm), and the measured specific surface emissivity ( $3.5 \text{ mW}^{-1} \text{ cm}^{-2} \text{ K}^{-1}$ ) to be at 0.2 K.

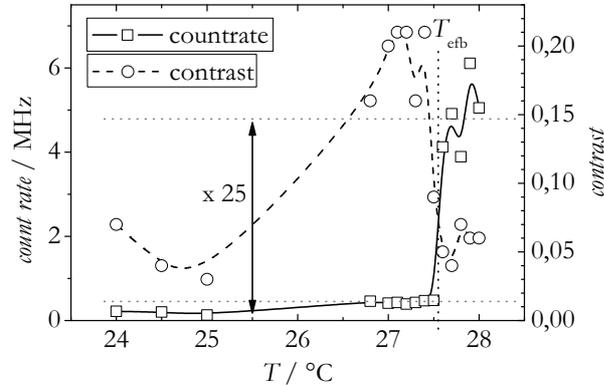

To determine the temperature offset in the investigated microemulsions, we performed measurements in IR-TDFRS using a microemulsion for which the phase diagram was precisely investigated. The used microemulsion is a composition of water, *n*-octane and tetraethylene glycol monodecyl ether ( $\text{C}_{10}\text{E}_4$ ) with a mass fraction of oil to water of 50/50. The phase diagram was measured in cooperation with the group of Prof. Strey and is shown in Fig.C.1. Measurements in IR-TDFRS were performed with a mass fraction of surfactant to water at  $\gamma = 0.154$  wt to determine the upper phase boundary from  $1\phi$  to  $\bar{2}\phi$  as a measure of the intensity of the diffracted read-out beam. The boundary temperature

**Figure C.1.:** The phase diagram of  $H_2O/C_8/C_{10}E_4$ . The mass fraction of water to n-octane is 50/50. The temperature is plotted versus the mass fraction of surfactant to water. At  $\gamma = 0.154$  wt (dotted vertical line) the efb was determined at  $T = (27.85 \pm 0.05)^\circ\text{C}$  in a water bath. The insets sketch the microemulsion in the upper  $\bar{2}\phi$  region with an occurring water excess phase (A) and in the  $1\phi$  region (B).

was previously determined at  $T = 27.85 \pm 0.05^\circ\text{C}$ . It was expected that in the  $\bar{2}\phi$  region the light scattering is higher than in  $1\phi$  because the  $\bar{2}\phi$  region is turbid and the  $1\phi$  region is clear and transparent.

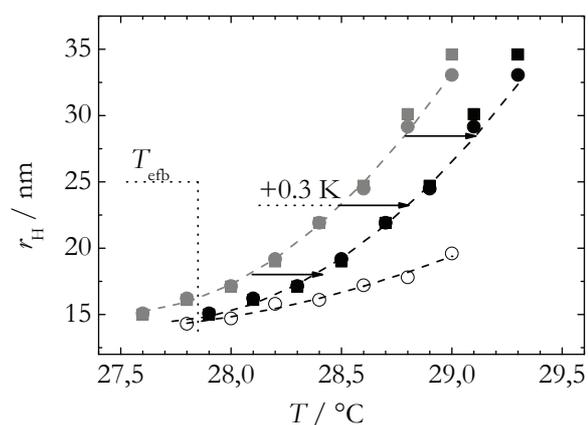

For our measurements in the IR-TDFRS setup the sample cell and the cell holder are thermostated to a temperature corresponding to where we find the  $C_{10}E_4$  microemulsion in the  $1\phi$  region. The microemulsion was equilibrated in the  $1\phi$  region under stirring and filled into the cell. We started the measurements at a temperature in the  $1\phi$  region below the upper boundary and increased the temperature stepwise by  $+0.1$  K. After each increase, the system was thermally equilibrated and we measured the intensity of the read-out beam for several minutes. The time average was taken. In the  $1\phi$  region, we read a count rate of approximately 190 kHz (at  $T < 27.50^\circ\text{C}$ ). Additionally, we measured a high contrast of the heterodyne signal which indicated that the incoherent light scattering was small. At  $T > T = 27.60^\circ\text{C}$  the intensity was strongly increased by a factor of 25 and reached 4700 kHz. Simultaneously the contrast dropped (see Fig.C.2). The interpretation is that the scattered light gained in intensity and was more pronounced than the intensity of the diffracted light. This indicated that the sample was in the upper  $\bar{2}\phi$  region. We determined the phase boundary at an average set temperature of  $T = 27.55 \pm 0.05^\circ\text{C}$ . This values is 0.3 K below the expected temperature and corresponds to a temperature

**Figure C.2.:** The temperature dependence of the count rate (open squares, left axis) and of the contrast (open circles, right axis) is shown for the heterodyne intensity signal in the IR-TDFRS setup for the investigated  $\text{H}_2\text{O}/\text{C}_8/\text{C}_{10}\text{E}_4$  microemulsion. The determined phase transition from  $1\phi$  to  $2\phi$  is found at  $T = 27.55\text{ }^\circ\text{C}$  (vertical dotted line). The horizontal dotted lines are guides to the eyes and mark the average count rates in  $1\phi$  and  $2\phi$ .

offset in the IR-TDFRS setup which needs to be considered, if microemulsion systems are measured in this setup. To our best knowledge, we cannot determine how far the temperature offset changes with the water content in the microemulsion but we assume that the temperature offset can be adopted to all microemulsion samples.

We compared the hydrodynamic radius of a  $\text{C}_8/\text{C}_{10}$  (50/50)-microemulsion determined by IR-TDFRS and DLS to check if the determined temperature offset allows a reliable data analysis. In Fig.C.3, the grey colored solid symbols present the original data from IR-TDFRS measurements and the black colored points are shifted in temperature by  $+0.3\text{ K}$ . Including this offset, the IR-TDFRS data fits with DLS data in the vicinity of the *efb* (dotted vertical line). To exclude systematic deviations in the hydrodynamic radius, the concentration process in the IR-TDFRS data was additionally analyzed using the Kohlrausch-Williams-Watts (KWW) method, which was used to analyze the DLS data. The difference between both, the standard (squares) and the KWW method (circles), is negligible and in the order of the error bars at low temperatures.

**Figure C.3.:** The temperature dependence of the hydrodynamic radius is plotted for a  $H_2O/C_{8/10}$  (50/50)/ $C_{12}E_5$  microemulsion measured by IR-TDFRS (solid symbols) and DLS (open symbols). The radius without (grey) and with the temperature offset (black). The vertical dotted line marks the efb.

---

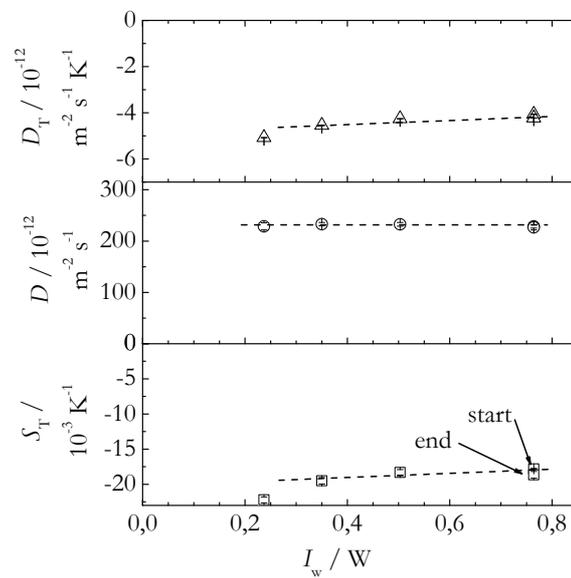

## INFLUENCE OF WRITING LASER POWER IN THE TDFRS SETUP

---

Both TDFRS setups use interfering laser beams to write an optical grating into the sample. The classical TDFRS setup uses a 488 nm Ar-laser with a light intensity of 300 mW, the IR-TDFRS setup works with a 980 nm laser with an output of 1000 mW. A higher light intensity is required for the aqueous samples in the IR-TDFRS setup due to the lower absorption ( $\alpha_{\text{ir}} = 0.18 \text{ cm}^{-1}$ ) in comparison to the dye-containing samples in the classical setup with  $\alpha_{\text{class}} = 2.0 \text{ cm}^{-1}$  which is of factor 10 higher. The main question is in how far the Soret coefficient is affected by the laser intensity.

We investigated the dependence of the thermal diffusion behavior on the light intensity in the classical TDFRS setup as the Ar-laser was easily to tune. A mixture of  $\text{C}_8\text{G}_1/\text{H}_2\text{O}$  with a surfactant mass fraction of 0.02 wt was used to which dye was added such that an optical density of  $2.47 \text{ cm}^{-1}$  was achieved. We performed measurements at  $15 \text{ }^\circ\text{C}$  and varied the light intensity from  $I_w = 237 \text{ mW}$  to  $764 \text{ mW}$ . The minimum intensity was slightly higher than the lasing threshold, whereas  $764 \text{ mW}$  was close to the maximum achievable output power of the Ar-laser. In Fig.D.1 the Soret and diffusion coefficients are plotted versus the light intensity. The measurements started at the highest light intensity. After each measurement, the intensity was stepwise decreased until the lowest light intensity was reached. Finally, the highest intensity measurement was repeated to ensure that the sample did not suffer from evaporation meanwhile.

An almost intensity independent behavior was observed for the mass diffusion coefficient,

**Figure D.1.:** Influence of the light intensity of the writing laser in the classical TDFRS setup on the Soret and diffusion coefficients. The sample is a  $\text{C}_8\text{G}_1/\text{H}_2\text{O}$  solution with  $\gamma_a = 0.02 \text{ wt}$  at  $15 \text{ }^\circ\text{C}$ . The first measurement (labeled as start) at  $764 \text{ mW}$  was repeated to check for evaporation effects (labeled as end) after measurements at different laser light powers were performed.

while the thermal diffusion and Soret coefficient decreased with decreasing intensity below 300 mW. Above this value, they were independent from changes in the light intensity. This confirmed that the experimentally used light intensity, which varied between 300 mW and 600 mW as a consequence of the aging process of the laser, did not influence the thermal diffusion behavior of the investigated samples.

PURITY OF  $C_8G_2$ 

The extremely low *cmc*, which was determined by the group in Köln for  $C_8G_2$ , was probably a consequence of impurities because the other determined critical micelle concentrations agreed with literature values, so that we could assume that the setup was reliable. In this chapter we want to discuss, why the surfactant is especially sensitive to impurities.

In the case of the glucosides, traces of *n*-octanol or further amounts of poly-glucosides were expected. The manufacturer pointed out that the amount of *n*-octanol was negligible as the surfactant was lyophilized. Hence, we focused on the determination of traces of poly-glucosides or other impurities by HPLC-MS and an absorption method.

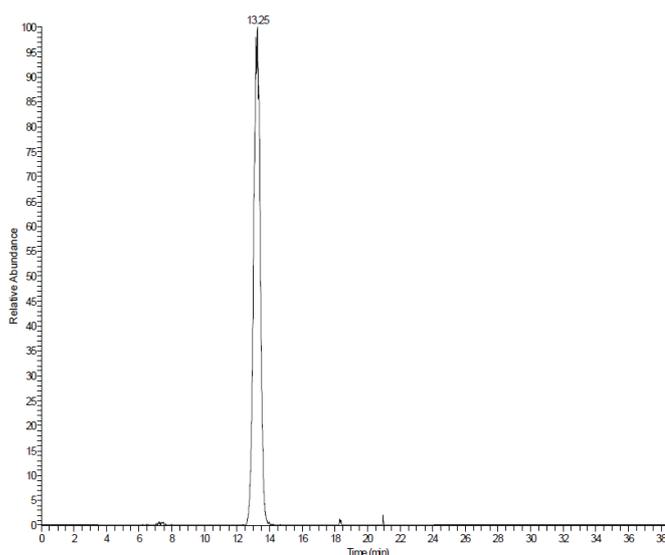

HPLC-MS (high performance liquid chromatography with coupled mass spectroscopy) measurements were performed by Dr. Björn Thiele (ZCH, FZ Jülich), and indicated a low level of impurities. It was shown by Billian [372] that the alkyl-polyglucosides and their monomers, which were assumed to be present in the sample, are separable with this technique. For the preparation of the sample, 10.4 mg of  $C_8G_2$  were dissolved in 10 ml pure water and diluted up to 230  $\mu$ M before filling in the column. The applied flow rate in the columns was between 250  $\mu$ l/min (column II) and 700  $\mu$ l/min (column I). The required mass-to-charge ratio for the mass spectroscopy was accomplished by electrospray ionization and set to  $m/z=472$  which related to the solution  $[M + NH_4]$  without HPLC. Once the mass spectroscopy parameters were calibrated, MS was connected to the HPLC eluent flow.

**Table E.1.:** Specifications Columns of the HPLC method. HPLC-system: Agilent 1100. MS-system: Thermo Electron TSQ Quantum.

Figs.E.1 and E.2 illustrate the relative abundance versus time measured with different columns. Details about the columns are given in Tab.E.1. The main peak in Fig.E.1 at 13.25 min (Fig.E.2: at 17.17 min) marks the eluting C<sub>8</sub>G<sub>2</sub>. Another shorter peak at smaller times in Fig.E.1 indicates a relatively lighter component, and the presence of two peaks at later times indicate larger components. The relative intensity of these secondary peaks is less than 2 % and only the most intense peak in Fig.E.1 at 20.9 min is also detected with column II in Fig.E.2 at 26.2 min.

The results promised only a low amount of impurities in the C<sub>8</sub>G<sub>2</sub> sample but it could

**Figure E.1.:** The time resolution of the elute from HPLC-MS method using column I (see Tab.5.1). The main peak at 13.25 min corresponds to *n*-Octyl  $\beta$ -D-maltopyranoside.

**Figure E.2.:** The time resolution of the elute from HPLC-MS method using column II (see Tab.5.1). The main peak at 17.17 min corresponds to *n*-Octyl  $\beta$ -D-maltopyranoside.

be expected that the impurities went to the interface and caused a change of the *cmc*. Depending on the column type, several smaller peaks were observed which could not be identified to a certain component.

## Glossar

$A$	amplitude of the heterodyne signal
$A$	area (only STM)
$A^*$	normalized amplitude
$A_{efb}$	amplitude of the heterodyne signal at the efb
$A_{head}$	area per surfactant head group
$A_{min}$	area per surfactant head group in a micelle
$A_T$	temperature grating
$a$	single point in the Taylor series
$a_c$	area per molecule in the particle-solvent interface
$a, b$	parameter of surface tension measurements
$B_1, \beta$	dimensionless instrument parameters (DLS)
$C_1, C_2$	parameters of the Taylor series
$c_1, c_2, c$	principle curvatures of the amphiphilic film
$C_x$	n-alkane of the type $\text{CH}_3 - (\text{CH}_2)_{(x-2)} - \text{CH}_3$
$cmc$	critical micelle concentration
$cmt$	critical micelle temperature
$D$	mass diffusion coefficient
$D_T$	thermal diffusion coefficient
$d$	the fringe spacing
$d_{eff}$	effective diameter of the sticky hard spheres
$d_{sample}$	optical length of the sample cell
$d_{water}$	optical length of the water cell
$d\Sigma/s\Omega$	differential cross section
$E_{ec,inc}$	coherent, incoherent part of the electrical field
$F$	correction factor for STM
$G$	Gibbs free energy
$g_1$	field-time-correlation function
$g_2$	intensity-time-correlation function
$h$	Planck constant
$I$	measured light intensity
$I(q)$	scattered intensity
$I_b$	background intensity
$I_{bg}$	scattered background intensity
$I_{ec}$	scattered intensity from the empty cell
$I_{hetero}$	heterodyne intensity
$I_{homo}$	homodyne intensity
$I_{sample}$	scattered intensity from the sample
$I_w$	the writing intensity
$I_{water}$	scattered intensity from the water cell
$I_\phi, I_{\phi+\pi}$	detected intensities in the TDFRS setup
$J_{1,2}$	mass flux

$J_Q$	heat flux
$k_B$	Boltzmann constant
$\underline{k}_{i,s}$	field vector of incident / scattered beam
$k_s$	thermal conductivity of the sample
$L$	phenomenological coefficient
$l$	length of the absorption cell
$l_{fluid}$	range of the colloid-solvent interaction
$M$	molar mass
$m$	mass
$n$	refractive index
$n_0$	refractive index of the solvent
$N$	number density of particles
$N_A$	Avogadro constant
$n_C$	alkane-to-surfactant ratio
$n_{core}$	refractive index of an inner droplet core
$n_{droplet}$	refractive index of spherical microemulsion droplet
$n_h$	hydration number
$n_{shell}$	refractive index of outer surfactant shell of a droplet
$n_w$	refractive index of the window of the absorption cell
$OD$	optical density
$P(q)$	form factor
$P_\zeta(t)$	Taylor function of $\zeta_{het}$
$p$	pressure
$p_0, p_1$	parameters of the Taylor series
$Q$	heat
$q$	wave vector in the TDFRS setups
$R$	universal gas constant
$r_H$	hydrodynamic radius
$r_{SANS}$	mean droplet radius (SANS)
$S$	entropy
$S(q)$	structure factor
$S_T$	Soret coefficient
$S_T^*$	normalized Soret coefficient
$S_T^\infty$	$S_T$ at infinite high temperature
$S_T^{w,inf}$	$S_T$ at infinite high concentration
$s$	optical path length of the flow cells
$T$	temperature
$T_0$	fit parameter for temperature
$T^*$	normalized temperature
$T^\pm$	sign inversion temperature
$T_{cp}$	cloud point temperature
$T_{ec}$	transmission from the empty cell
$T_{efb}$	temperature of the <i>efb</i>

$T_{ncb}$	temperature of the <i>ncb</i>
$T_{\text{sample}}$	transmission from the sample
$T_{\text{water}}$	transmission from the water cell
$t$	time
$t_{\text{decay}}$	exponential decay constant
$t_{\text{di}}$	thickness parameter of the diffuse interface
$U$	internal energy
$V_{\text{disp}}$	total volume per droplet
$V_x$	volume of component x
$v$	velocity
$v_c$	particle volume
$W$	work
$w_0, w$	concentration in equilibrium and in steady state. Assumption: $w_0 \approx w$
$w^*$	normalized concentration
$w_{B,A}$	mass ratio of the component A or B to the total mass
$w_{cmc}$	concentration at the <i>cmc</i>
$w_{\pm}$	sign inversion concentration
$X_j$	thermodynamic force
$\alpha$	absorption coefficient of the sample
$\alpha_s$	thermal expansion coeff. of the absorption cell side walls
$\alpha_T$	thermal diffusion factor, $\alpha_T = T \cdot S_T$
$\alpha_w$	thermal expansion coeff. of the absorption cell windows
$\alpha_V$	thermal diffusion coefficient
$\beta_{KWW}$	fit parameter (DLS)
$\Gamma$	decay rate (DLS)
$\Gamma_{\text{max}}$	maximum surface excess concentration
$\gamma_{b,a}$	mass ratio of surfactant to the oil (b) or to water (a)
$\epsilon_x$	dielectric constant of component x
$\zeta_{\text{het}}$	heterodyne signal in TDFRS
$\zeta_{\text{homo}}$	homodyne signal in TDFRS
$\eta$	viscosity
$\theta_{r,w}$	angle of the read-out, writing beams
$\lambda$	wavelength
$\mu$	chemical potential
$\rho$	density
$\rho_{\text{air}}^0$	density of air
$\rho_{\text{mix}}^0$	density of the mixture
$\sigma$	surface tension
$\sigma_0$	surface tension of pure water
$\sigma_{\text{exp}}$	measured surface tension
$\sigma_G$	standard deviation
$\tau_c$	process time of the concentration mode

---

$\tau_d$	decay time (DLS)
$\tau_{th}$	thermal diffusivity
$\phi_0$	volume fraction of droplets
$\phi_B$	volume fraction of the alkanes
$\phi_c$	internal interface
$\phi_{mon,b}$	monomeric dissolved $C_{12}E_5$ in oil
$\varphi_{chain}$	angle between surfactant chain unit and interface
$\varphi_{head}$	angle between surfactant head group and interface
$\varphi_{KWW}$	Kohlrausch-Williams-Watts function

## Danksagung

Mein aufrichtiger Dank gilt Herrn Prof. Reinhard Strey für die interessante Themenstellung, für die herzliche Aufnahme in seine Arbeitsgruppe und für die vielen Ideen, die diese Arbeit beflügelt haben.

Ganz persönlich danke ich Simone Wiegand für die aufopferungsvolle Unterstützung in den letzten drei Jahren bis zum letzten Satz dieser Arbeit. Sie betreute die Jülicher Experimente, gab Hilfestellungen beim Verfassen von Veröffentlichungen und Verlängerungsanträgen, und war jederzeit zur Diskussion bereit um Verständnisfragen zu erörtern. Ein nicht geringerer Dank gebührt den Kollegen des DFG-Projektes in Köln, Thomas Sottmann und Sascha Datta für die unzähligen Diskussionen in Köln, Jülich, aber auch des Nachts an der Neutronenquelle in Garching.

Ich möchte mich herzlich bei Jan Dhont bedanken, der es mir ermöglichte die Promotion im Forschungszentrums Jülich durchzuführen. Auf technischer Seite gilt meine Hochachtung Hartmut Kriegs. Mit ihm wurden beinahe zu häufig Hochspannungsverstärker, Laser und andere fehleranfällige Bauteile in den experimentellen Aufbauten gewechselt, ersetzt und justiert. Dieter Triefenbach und Hans Jürgen Hoffmann danke ich für die Unterstützung bei technischen Problemen; Sylvia de Waal und Karin Sellinghoff unterstützten mich in meiner Labortätigkeit. Marie Göcking räumte zuverlässig und stressfrei bürokratische Hürden aus dem Weg. Die Neutronenstreuungsmessungen in Garching wurden professionell von Henrich Frielinghaus begleitet.

Für die vielen fachlichen Diskussionen möchte ich mich bei Gerhard Nägele, Johan Buitenhuis, Peter Holmqvist, Peter Lang, Pavlik Lettinga, Gerd Meier, Wiebke Sager, Pablo Blanco und Pavel Polykov bedanken. Ich danke auch Kyongok Kang, Emmanuel Stiakakis, Donald Guu, Macro Heinen, Yunfei Jia, Christoph July, Gopinath Shanmugavadivelu, Karolina Tomczyk, Claudio Contreras-Aburto und Jing Zhang für die durchlebten Stunden innerhalb und außerhalb des Instituts. Zudem haben sich Michael Klein, Simon Rogers und Zilin Wang viel Mühe beim Korrekturlesen gegeben.

Ich blicke immer wieder gerne auf die vielen dienstlichen und vor allem auf die außerdienstlichen Treffen mit der Kölner Arbeitsgruppe zurück. Es stellte sich schnell heraus, dass man in der Uni nicht nur gut DFG-Projekte bearbeiten, sondern vorzüglich Grillen, Sport treiben, oder ein Bierchen trinken kann. Vielen Dank für die vielen gemeinsamen Stunden!

In meiner PhD-Zeit durfte ich meine Ergebnisse in der *International Helmholtz Research School of Biophysics and Soft Matter* präsentieren und an vielen interessanten Veranstaltungen teilnehmen.

Meiner Familie danke ich für die Geduld und die aufmunternden Worte in stressigen Zeiten.

## Erklärung

Ich versichere, dass ich die von mir vorgelegte Dissertation selbständig angefertigt, die benutzten Quellen und Hilfsmittel vollständig angegeben und die Stellen der Arbeit - einschließlich Tabellen, Karten und Abbildungen -, die anderen Werken im Wortlaut oder dem Sinn nach entnommen sind, in jedem Einzelfall als Entlehnung kenntlich gemacht habe; dass diese Dissertation noch keiner anderen Fakultät oder Universität zur Prüfung vorgelegen hat; dass sie - abgesehen von angegebenen Teilpublikationen - noch nicht veröffentlicht worden ist sowie, dass ich eine solche Veröffentlichung vor Abschluß des Promotionsverfahrens nicht vornehmen werde. Die Bestimmungen dieser Promotionsordnung sind mir bekannt. Die von mir vorgelegte Dissertation ist von Prof. Dr. R. Strey betreut worden.

---

Bastian Arlt

# Lebenslauf

## Zu meiner Person

Name	Bastian Arlt
Geburtsdatum, -ort	06.04.1981, Herdecke
Staatsangehörigkeit	deutsch

## Ausbildung

ab 05/2008	<b>Promotion</b> “ <i>Thermal Diffusion in binary Surfactant Systems and Microemulsions</i> ” Forschungszentrum Jülich GmbH und Universität zu Köln, Prof. Strey
09/2006 – 09/2007	<b>Diplomarbeit</b> “ <i>Consequences of a generalized Maxwell model for nonlinear flow</i> ” Technische Universität Berlin, Prof. Hess
05/2005 – 05/2007	<b>Wissenschaftliche Studentische Hilfskraft</b> Technische Universität Berlin, Prof. Hess
10/2001 – 01/2008	<b>Diplom Physik</b> Physik-Studium an der Technischen Universität Berlin 04/2004 Vordiplom 09/2007 Hauptdiplom
08/2000 – 05/2001	<b>Zivildienst</b> Medicus GmbH, Oranienburg
07/1987 – 06/2000	<b>Abitur</b> 1987 – 1988 Grundschule Blecher 1988 – 1991 Grotenburg Grundschule Krefeld 1991 – 1993 Gymnasium Fabritianum Krefeld 1993 – 2000 Marie-Curie-Gymnasium Hohen Neuendorf Leistungskurse: Physik und Mathematik
