Keywords: Ruthenium dihydrogen complexes / H/D exchange / CH activation / Deuteration / DFT calculations

Catalytic H/D-exchange reactions were studied with [Ru(dtbpmp)(η²-H₂)(H₂)] (1) as catalyst. Under mild reaction conditions (25–75 °C) a wide range of arenes and olefins undergo H/D exchange with [D₆]benzene. A preference for protons at sp² carbons was observed with conversions up to >90% and significant regioselectivity in certain cases. For more reaction insights NMR-based kinetic studies were performed with naphthalene as substrate, revealing an activation energy of 15.8 kcal mol⁻¹ for the H/D exchange at the β-position. Furthermore, the key steps of the reaction mechanism were investigated by means of DFT calculations for both model complexes (PMes₂ donor sites) and real catalysts (PtBu₂ donor sites). The calculations resulted in Gibbs's free activation energies in the range of 10–16 kcal mol⁻¹, indicating H/D exchange at the β-position of naphthalene to be clearly favoured over the α-position, which is in full accordance with the experimental observations.

Introduction

Activation of C–H bonds in hydrocarbons is one of the prominent challenges in modern homogeneous catalysis. For early evaluation of the potential of new catalyst precursors for this type of reaction, H/D-exchange processes are found to be useful for C–H bond cleavage and formation.[1–3] Other application fields of isotopic exchange reactions are well established, for example, in medicinal research and drug discovery processes where deuterated and tritiated labeled compounds are used to investigate metabolisms.[4–6] Furthermore, there is an increasing interest in mild and selective catalytic H/D-exchange processes from a fundamental and application-oriented view.

H/D exchanges catalyzed by transition metals are usually performed with D₂ or in deuterated organic solvents such as [D₆]benzene or [D₆]acetone, and in some cases deuterium oxide or [D₂]methanol can be used, unfortunately, in most cases the reaction temperatures are well above 100 °C or higher catalyst loadings are necessary.[4,7,8,9,10] Organometallic complexes of iridium, rhodium, and ruthenium show a particular promising potential as catalysts.[4,8,a,b,9c,d,10] As part of our ongoing interest in the catalytic properties of non-classical ruthenium hydrides, we have investigated several complexes of that type in recent years.[11,12] For monomeric complexes we included bulky mono-dentate phosphines and carbenes of NHC-type.[11,12a] With chelating bidentate phosphate ligands binuclear complexes were obtained, instead, bulky tridentate pincer ligands led to monomeric complexes.[12] For example [Ru(IMes)(PCy₃)(η²-H₂)₂-H₂] (2a) (IMes = 1,3-dimesityl-1,3-dihydro-2H-imidazol-2-ylidene) and [Ru(IMes)(η²-H₂)₂H₂] (2b) as carbene analogues of Chaudret's hexahydride [Ru(PCy₃)₂(η²-H₂)₂H₂] (3).[11] In contrast to 3, complexes 2a and 2b showed a very high activity for the H/D exchange between [D₆]benzene and several arenes. As recently communicated, we focus on the investigation in catalysis of ruthenium dihydrogen complexes bearing pincer-ligands with constrained geometry.[10,12b] The complex [Ru(dtbpmp)(η²-H₂)₂H₂] (1) (dtbpmp = 2,6-bis(di-tert-butylphosphanyl)methyl)imidazole) is readily accessible in good yields using the direct hydrogenation route shown in Scheme 1.[12] Complex 1 was found to catalyze the H/D exchange efficient at 50 °C. It should be noted that catalytic deuterium incorporation into

Scheme 1. Synthesis of 1.[12b]
hetero aromatic compounds such as thiophene, 2,5-dimethylfuran and indol occurred very efficiently with D₂O as the deuterium source.[10]

During these studies, it was observed that complex 1 is also an active catalyst for the H/D exchange between [D₆]benzene and aromatic substrates such as toluene 4 (Scheme 2).[10,12b] In the present work we discuss the results of catalytic H/D exchange reactions between arenes and [D₆]benzene with the non-classical hydride complex [Ru(dbtpmp)(η⁴-H₂)H₂] (1) as catalyst precursor. At 50 °C, deuterium is effectively transferred from the solvent C₆D₆, into arenes with a significant regioselectivity for certain cases. The substrate scope included arenes, olefins and ferrocene and we complemented our previous mechanistic investigations,[10] by including NMR kinetics and additional DFT calculations.

Scheme 2. Catalytic H/D exchange of aromatic compounds using C₆D₆ as the deuterium source and complex 1 as catalyst precursor. Reaction conditions (under argon): substrate 4 – 13: 1.0 – 1.6 mmol; 1 mol-% Ru-cat., 1, C₆D₆ (0.6 mL), C₆H₁₂ (0.05 mL), t = 3 d; reaction temperature: T = 50 °C; see Exp. Sect. for details. The values give the overall incorporation at the indicated positions.

Results and Discussion

As depicted in Scheme 2, selective H/D exchange occurred when treating toluene 4 with 1 mol-% of precatalyst 1 at 50 °C within three days. The incorporation took place with a clear preference for the meta position (87%), while the para protons was much lower deuterated (28%) and no significant incorporation was detected in the ortho position. The methyl group remained unreactive under the present conditions. In accordance to this observation, also other arenes were deuterated by treatment with 1 under similar conditions. Again, a significant chemo- and regio-selectivity was observed in certain cases. o-Xylene 5 was exclusively deuterated in the positions which are meta to the methyl groups (>95%). In case of m-xylene 6 the regio-selectivity is largely the same. The proton in the position that is meta to both methyl groups undergoes almost completely H/D exchange (93%). The total sum of the deuterium incorporation is low (15%) for all other aromatic positions as well for methyl groups (6%). No H/D exchange was detectable with mesitylene 7 as substrate, even at higher catalyst loadings (2 mol-%). The treatment of naphthalene 8 under the same conditions as for 4 resulted preferably in β-deuteration (90%) with a low amount of α-deuteration (18%).

The deuterium incorporation in phenanthrene 9 is also high and occurs almost exclusively in the two positions C3 and C4 (94%). Interestingly, the heteroaromatic isoquinoline 10 was not deuterated under the conditions used in this study. This might be a result of the stronger coordination of the nitrogen functionality in isoquinoline 10 supported by DFT calculations for the two isomeric complexes 10a and 10b (Figure 1).

The two isomers should be the ones that compete in the reaction mechanism for the H/D exchange (vide infra).[10] The calculations show 10b to be more stable than 10a by 19.6 kcal/mol. As a result the reaction only can take place if 10b isomerizes to 10a, which is an event that involves decoordination of isoquinoline and re-coordination in C–H binding mode, which does not seem to be possible under the reaction conditions used in this work.

Aromatic substrates like styrene 11 or indene 12 are also highly deuterated with a very different chemo- and regio-selectivity. The olefinic double bond is deuterated preferentially in styrene 11, with terminal positions being most reactive. Almost complete deuteration was observed in both terminal vinylic positions under standard conditions (86–88%). Very high incorporation (75%) was also obtained in the ortho and para positions of the aromatic ring. For indene 12 the deuteration is higher in the five-membered ring (69–89%) than in the six-membered ring. Also the incorpo-
Catalytic H/D Exchange under Mild Conditions

Figure 2. Time-resolved $^1$H-NMR-monitoring of the H/D exchange in naphthalene 8. Catalyst loading for 1: 4 mol-%, $T = 70$ °C; conversion: 24% ($\alpha$), 90% ($\beta$) after 240 min.

The properties of the catalytic system were studied in more detail with naphthalene 8. As previously reported for the D$_2$O system, also in the present system the reaction was not influenced by the addition of mercury.[10] This indicates a molecular organometallic mechanism.[13] Under the conditions of Scheme 2 the results were identical within the experimental order in the presence of mercury (Hg/Ru = 10:1; $\alpha$: 18%; $\beta$: 92%).[13] The kinetics of the reaction were than investigated by monitoring the H/D exchange at the $\beta$-position by $^1$H NMR spectroscopy at different temperatures and catalyst loadings. Figure 2 shows the strong signal decrease of the $\beta$-positions, the lower decrease of the $\alpha$-positions and the increase of the benzene signal due to the H/D exchange. The increase of the deuterium incorporation at the $\beta$-position with precatalyst 1 (7 mol-%) at 50 °C resulted in deuterium incorporation of 79% after 6.5 h and 90% at 24 h respectively. In a second independent run a deuterium incorporation of 87% (6.5 h) and 95% (24 h) was obtained. Only 18% of the $\alpha$-positions were exchanged at that stage.

A detailed analysis of the spectra between 20 and 70 min reaction time (< 30% conversion) revealed an initial rate of $1.23 \times 10^{-6}$ mol L$^{-1}$ min$^{-1}$ for a reaction with 2 mol-% of 1 at 50 °C (Figure 3). The rate increased to $2.77 \times 10^{-6}$ mol L$^{-1}$ min$^{-1}$ upon doubling the catalyst loading to 4 mol-%. Further increase to 7 mol-% gave a rate of $3.31 \times 10^{-6}$ mol L$^{-1}$ min$^{-1}$. From a double logarithmic plot of these data (Figure 4), a formal reaction order of 0.8 can be deduced for catalyst 1. The data are most consistent with a first-order dependence up to concentrations corresponding to 4 mol-% and a deviation at higher loadings. This may be at least attributed to the formation of unreactive hydride bridged dimers.[12a,14]

The influence of the reaction temperature was investigated at 4 mol-% loading of 1 in the range of 40–70 °C (Figure 5). The slope of the nearly linear increase between 20 and 80 min reaction time was used to determine the acti-
viation energy of the process. From the Arrhenius plot, shown in Figure 6, the apparent activation energy is derived as \( E_A = 15.8 \text{ kcal mol}^{-1} \).

Figure 5. Temperature-dependent conversion/time profiles of the \( \beta \)-deuteration of naphthalene \( 8 \) catalyzed by \([\text{Ru(dtbpmp)}(\text{H}_2)\text{H}_2]\) (I). Conditions: time-resolved \( \text{H-NMR}-\)monitoring, catalyst loading: \( 4 \text{ mol\%} \), \( T = 40 - 70 \degree \text{C} \).

Figure 6. The Arrhenius plot of the \( \beta \)-deuteration catalyzed by \([\text{Ru(dtbpmp)}(\text{H}_2)\text{H}_2]\) (I).

We have very recently reported a reaction mechanism for the \( \text{H/D} \) exchange for benzene and toluene based on DFT calculations.\(^{[10]}\) The mechanism relies on \( \sigma \)-bond metathesis as the key step. In a four-centre transition-state, one arene bonded hydrogen centre reacts with a metal bonded hydride centre forming metal bonded \( \text{H}_2 \), while the carbon atom of the arene forms a single bond with the metal. In the present study, we have extended these calculations to the exchange of naphthalene as substrate in order to validate the consistency of this mechanistic model with the experimental results. Our previous study had shown that the difference between the activation energies of a \( \text{H/H} \)-transfer is roughly 1 \text{ kcal mol}^{-1} \) lower than a \( \text{H/D} \)-transfer. Therefore only \( \text{H/H} \)-transfer processes are considered in this work for simplicity. The corresponding local minima (reactants \( 14_{\alpha}, 14_{\beta} \) and products \( 15_{\alpha}, 15_{\beta} \), a for \( \alpha \) isomer, \( b = \beta \) isomer) as well as transition states (\( 14_{\alpha,\beta} \)-\( 15_{\alpha,\beta} \)) were located for complexes containing the real ligand and for a model ligand, in which the \( \text{tBu} \) groups of the real ligand were replaced by \( \text{Me} \) groups. The reason for computing the same reaction step for both types of ligands was to assess the steric influence of the real ligand and/or to find out if electronic reasons also play a role in this reaction. Scheme 3 shows the key steps of the exchange process for both ligand types: \([\text{Ru-}(\text{dMepmp})(\eta^2-\text{H}_2)(\text{C}_{10}\text{H}_8)](14_r) \) (\( r \) for model ligand) as well as the real catalyst complex \([\text{Ru(dtbpmp)}(\eta^2-\text{H}_2)(\text{C}_{10}\text{H}_8)](14) \) (\( \epsilon \) for real ligand). Key structural parameters of the real complexes are shown in Figure 7.

Complexes with the real ligand are discussed first (reaction of \( 14_{\alpha} \) and \( 14_{\beta} \) to \( 15_{\alpha} \) and \( 15_{\beta} \), respectively, Figure 7): for the real complexes the relative stabilities of the reactants show the \( \alpha \)-isomer to be slightly more unstable than the \( \beta \)-isomer. However, this difference is small, i.e. at the reaction temperature chosen in this work both the \( \alpha \)- and the \( \beta \)-isomer should be present in solution. In the transition states the planes of the naphthalene rings are rotated relative to the planes which are formed by the ruthenium centre, the two hydrogen centres attached to it and the nitrogen atom of the pincer backbone (i.e. rotation about the Ru–C bond that is being formed, Figure 7). This rotation is necessary for the molecules to generate the appropriate geometry that enables hydrogen transfer. For the \( \beta \)-isomer (\( 14_{\alpha,\beta} \)-\( 15_{\alpha,\beta} \)) the naphthalene ring is rotated about the C1–C2–H1–H2 bond by 94\degree. However, for the \( \alpha \)-isomer (\( 14_{\alpha,\beta} \)-\( 15_{\alpha,\beta} \)) the naphthalene ring can only be rotated up to a value of 83\degree, on further rotation the repulsive interactions between the remote phenyl ring of that naphthalene unit and the methyl groups of one \( \text{tBu} \) substituent will become too strong. Accordingly, the transition state geometry of the \( \alpha \)-isomer is less ideal resulting in a significantly higher activation energy (15.0 \text{ kcal mol}^{-1} \) relative to the reactant) compared to the \( \beta \)-isomer (10.4 \text{ kcal mol}^{-1} \) relative to the reactant).\(^{[15]}\)

Upon replacement of the \( \text{tBu} \) groups in the real ligands by \( \text{Me} \) groups in the model ligands the steric strain should
be minimized, i.e. the steric influence on the activation energies should be lowered. For the reaction of 14 to 15 the calculated Gibb’s free activation energy amounts to 7.4 kcal/mol (relative to the reactant), while for the β-isomer it is 5.1 kcal/mol (Scheme 3), which indicates the steric factors play indeed a role in this reaction. Additionally and in contrast to the real complexes in the model complexes the naphthalene units of both isomers are rotated significantly further than the rotation in the real complexes. Also the rotation in the model complexes reaches approximately the same extent (100° and 103° for the α- and the β-isomer, respectively; not shown in Figure 7). These values are very similar to the corresponding benzene complex (100°, not shown) indicating that in the model complexes there is no sterically induced hindrance for this rotation that is associated with the remote part of the naphthalene ring. This is reflected in the energy difference of the two transition states: In the model complexes the difference is 2.3 kcal/mol, while for the real complexes (vide supra) the difference is 4.6 kcal/mol. Therefore it is reasonable to assume that both electronic and steric factors play a role in this reaction.

The structures of the transition states indicate furthermore that in the case of the α-isomer the reaction has not made as much progress as for the β-isomer. For instance, in the real complexes the Ru–C distance of the forming Ru–C bond is significantly longer (2.239 Å) in the α-isomer than in the β-isomer (2.207 Å). The H–H bond, which is being formed reflects this tendency as well. In the α-isomer the H–H distance is 1.603 Å, while in the β-isomer the distance is slightly shorter (1.592 Å) indicating as well that the process of bond formation has advanced further. Re-optimization of the real complexes in the presence of benzene as the solvent showed no significant changes in the energy profiles, indicating the solvent to have no drastic influence on the reaction. According to these results one would expect a significantly higher deuterium incorporation in the β-position, with no significant incorporation in the α-position. This is in full accord with our experiments which showed that there is a clear preference of the β-position (up to >95% deuterium) with respect to α-deuteration (<20%), which can be influenced by catalyst loadings, temperature and reaction time as previously discussed. Overall the experimental and computational data generate a consistent picture and show that the process is facile. Also the computationally derived activation barriers reflect the experimentally regioselectivity nicely. This regioselectivity has electronic grounds which are further improved by steric hindrance exerted by the tBu groups at the ligand.
Conclusions

We have shown that the non-classical ruthenium hydride complex 1 is an effective catalyst for the H/D exchange between arenes, olefins and [D₆]benzene at mild conditions. The incorporation shows significant chemo- and regioselectivity in certain cases which is in agreement with our previous investigations with D₂O as deuterium source.[10] In conclusion, the H/D exchange is independent from the deuterium source. The NMR-kinetics resulted in an activation energy of 15.8 kcal/mol for the H/D exchange.

Experimental Section

General: All reactions were performed under Ar and H₂ atmospheres using Schlenk or glove box techniques. Solvents and substrates were purchased from Aldrich, Acros and Strem and were purified according to standard procedures.[16] The PNP ligand dtbppm was synthesised according the procedures by Milstein and Hartwig.[17,18] The syntheses of the ruthenium complexes were carried out in a thick-walled Büchi Miniclavé made of glass, similar to a Fischer–Porter bottle, via the direct-hydrogenation route starting from the [Ru(cod)(η¹-C₅H₅)₂] complex.[10,12]

Caution! The use of pressurised gases can be hazardous and must only be carried out with suitable equipment and under appropriate safety precautions.

The deuterium incorporation was quantified by integration of the substrate/product signals in the 1H NMR spectra in ratio to internal standard cyclohexane. The deuterium were verified by combination of 13C-NMR and 2H NMR spectroscopy. The NMR spectra were recorded on Bruker AMX-300, Bruker AMX-400 (NMR kinetics) and Bruker DMAX 600 (FH NMR) spectrometer.

Procedure for Catalytic H/D Exchange between Aromatics and [D₆]Benzene with [Ru(dtbbpp)(η¹-C₅H₅)₂] as Catalyst, Exemplified for Toluene 4: A Teflon®-capped Young NMR tube was filled with the catalyst 1 (5 mg, 0.01 mmol, 1 mol-%), then 0.6 mL of C₆D₆ was added. The substrate 4 (92 mg, 1.0 mmol) and 0.05 mL cyclohexane (internal standard) were added. The 1H NMR spectrum was measured immediately in order to determine the substrate/internal standard ratio as starting point of the reaction, the mixture was kept for three days at 50 °C, afterwards it was cooled to room temp. and the 1H- and 2H NMR spectra were measured (manual lock to [D₆] benzene; conversion: 87% (α), 90% (β), < 5% (ortho), 1% (meta), 1% (Me). 1H NMR (300 MHz, C₆H₆/[D₆]benzene, 25 °C, before H/D exchange): δ = 7.6 (17.1, α), 7.2 (16.3, β), 1.4 (100.0, C₆H₁₂, internal standard) ppm. 2H NMR (600 MHz, C₆H₆/[D₆]benzene, 25 °C, after H/D exchange): δ = 7.7 (residue, α, 7.3) ppm. 31P NMR (122 MHz, C₆H₆/[D₆]benzene, 25 °C, after H/D exchange): δ = 108.0 (s, main signal) ppm. – c) Ru-cat 1 (7 mol-%), T = 50 °C, substrate: 0.5 mmol, 0.6 mL C₆D₆, 0.05 mL C₆H₁₂; conversion: 79% (β)/(6.5 h), 90% (β)/(24 h). d) Ru-cat 1 (7 mol-%), T = 50 °C, substrate: 0.5 mmol, 0.6 mL C₆D₆, 0.05 mL C₆H₁₂; conversion: 87% (β)/(6.5 h), 95% (β)/(24 h). e) Ru-cat 1 (4 mol-%), T = 70 °C, substrate: 0.5 mmol, 0.6 mL C₆D₆, 0.05 mL C₆H₁₂; conversion: 65% (β)/(1.3 h), 90% (β)/(24 h). f) Ru-cat 1 (4 mol-%), T = 60 °C, substrate: 0.5 mmol, 0.6 mL C₆D₆, 0.05 mL C₆H₁₂; conversion: 30% (β)/(1.3 h), 64% (β)/(4 h). g) Ru-cat 1 (4 mol-%), T = 45 °C, substrate: 0.5 mmol, 0.6 mL C₆D₆, 0.05 mL C₆H₁₂; conversion: 21% (β)/(1.3 h), 48% (β)/(4 h). h) Ru-cat 1 (4 mol-%), T = 40 °C, substrate: 0.5 mmol, 0.6 mL C₆D₆, 0.05 mL C₆H₁₂; conversion: 11% (β)/(1.3 h), 22% (β)/(8 h). i) Ru-cat 1 (2 mol-%), T = 50 °C, substrate: 0.5 mmol, 0.6 mL C₆D₆, 0.05 mL C₆H₁₂; conversion: 15% (β)/(1.2 h). j) Ru-cat 1 (4 mol-%), T = 50 °C, substrate: 0.5 mmol, 0.6 mL C₆D₆, 0.05 mL C₆H₁₂; conversion: 28% (β)/(1.3 h), 54% (β)/(4 h).

Catalytic H/D Exchange under Mild Conditions

Ru-cat 1: 5 mg (0.01 mmol, 1 mol-%), T = 50 °C, substrate: 178 mg (1.0 mmol), 0.5 mL C₆D₆, 0.05 mL C₆H₁₂, t = 3 d; conversion: < 5% (C1), 7% (C2), 40% (C3), < 5% (C5). ³H NMR (300 MHz, C₆H₁₂/[D₆]benzene, 25 °C, before H/D exchange): δ = 8.4 (17.6, C5), 7.6 (15.9, C2), 7.4 (16.4, C1), 7.3 (31.5, C3/C4), 1.4 (100.0, C₆H₁₂, internal standard) ppm. ³H NMR (600 MHz, C₆H₁₂/[D₆]benzene, 25 °C, after H/D exchange): δ = 7.3 (3.3, m), 6.8 (50.3, alp), 6.3 (15.9, x), 5.3 (18.1, a), 4.8 (17.1, b), 1.2 (100.0, C₆H₁₂, internal standard) ppm. ²H NMR (300 MHz, C₆H₁₂/[D₆]benzene, 25 °C, after H/D exchange): δ = 7.0 (29.0, m), 6.8 (12.8, alp), 6.3 (10.4, x), 5.3 (2.5, a), 4.8 (2.0, b), 1.3 (100.0, C₆H₁₂, internal standard) ppm. ²H NMR (600 MHz, C₆H₁₂/[D₆]benzene, 25 °C, after H/D exchange): δ = 7.3 (m), 7.1 (alp), 6.6 (x), 5.6 (a), 5.1 (b) ppm.

Indene 12

Ru-cat 1: 5 mg (0.01 mmol, 1 mol-%), T = 50 °C, substrate: 116 mg (1.0 mmol), 0.5 mL C₆D₆, 0.05 mL C₆H₁₂, t = 3 d; conversion: 62% (C1, C2), 27% (C3, C6), 69% (C7), 89% (C8), 76% (C9). ³H NMR (300 MHz, C₆H₁₂/[D₆]benzene, 25 °C, before H/D exchange): δ = 7.3 (31.6, C3, C6), 7.3–7.1 (33.2, C3, C6), 6.7 (17.1, C7), 6.2 (14.9, C8), 3.0 (42.0, C9), 1.4 (100.0, C₆H₁₂, internal standard) ppm. ³H NMR (300 MHz, C₆H₁₂/[D₆]benzene, 25 °C, after H/D exchange): δ = 7.3 (23.1, C1, C2), 7.3–7.1 (12.7, C3, C6), 6.7 (5.5, C7), 6.2 (1.6, C8), 3.0 (10.0, C9), 1.4 (100.0, C₆H₁₂, internal standard) ppm. ²H NMR (300 MHz, C₆H₁₂/[D₆]benzene, 25 °C, after H/D exchange): δ = 7.3 (C1, C2), 7.1–7.0 (C3, C6), 6.7 (C7), 6.2 (C8), 3.0 (C9) ppm.

Ferrocene 13: Ru-cat 1 (5 mg, 0.01 mmol, 1 mol-%), T = 50 °C, substrate: 186 mg (1.0 mmol), 0.6 mL C₆D₆, 0.05 mL C₆H₁₂, t = 3 d; conversion: 25%. ³H NMR (300 MHz, C₆H₁₂/[D₆]benzene, 25 °C, before H/D exchange): δ = 4.0 (35.2, Cp-H), 1.4 (100.0, C₆H₁₂, internal standard) ppm. ³H NMR (300 MHz, C₆H₁₂/[D₆]benzene, 25 °C, after H/D exchange): δ = 3.7 (26.5, Cp-H), 1.4 (100.0, C₆H₁₂, internal standard) ppm. ²H NMR (600 MHz, C₆H₁₂/[D₆]benzene, 25 °C, after H/D exchange): δ = 4.0 (Cp-D) ppm.

Computational Studies: The calculations reported herein were carried out with the Gaussian 03 program series (revision C02).[10] Local minima and transition states were calculated employing the B3LYP hybrid functional.[10] For model complexes (i.e. Me substitutes at P) all nonmetal atoms were calculated using the TZVP basis set by Ahlrichs et al.[21] in the implementation that is used in the Gaussian03 program, while for ruthenium the Stuttgart/Dresden (311111/221111/411) basis set and associated ECP was used.[23] This basis set is denoted B1. For real complexes (i.e. tBu substituents at P) all nonmetal atoms were calculated using the 6-31G(d) basis set.[24] For the hydrogen centres bonded to the metal (2 centres) and the hydrogen centre of the naphthalene taking part in the reaction (1 centre) polarization functions were added, so that these 3 hydrogen centres were calculated with the 6-31G(d,p) basis set. For the ruthenium centre a (441/2111/311/1) basis set,[25] together with the united atom topological model for radii. Extra spheres for hydrogen were added for the hydrogen centres present at the Ru center and the hydrogen centre of the naphthalene involved in the reaction. During the geometry optimizations and the subsequent frequency calculations, the calculation of dispersion solute-solvent interaction energy, of repulsion solute-solvent interaction energy, and of the cavitation energy were switched off.

The Mynott group (R. Ettl, C. Wirtz, W. Wisniewski, M. Stachschel, B. Waßmuth and R. Mynott) is acknowledged for NMR and IR experiments. RWTH Aachen, Max-Planck-Gesellschaft and German–Israeli Project Cooperation (DIP G7.1) are gratefully acknowledged for financial support. We are also grateful for generous allocation of computer time by the Computation and Communication Centre of the RWTH Aachen.

The difference of the experimentally derived activation energy for the β-isomer (15.8 kcal/mol) and the calculated one (10.4 kcal/mol) is assumed to be a result of a mixture of different experimental and theoretical error sources: The experimental error for the determination of $E_a$ by NMR spectroscopy is estimated to be $\pm 2$–3 kcal/mol. It was shown before that the calculation of H, H and H, D-exchanges yield to differences in activation energies of ca. 1 kcal/mol, with the H, D-exchange yielding the higher activation energies. However, and presumably most important the combination of the B3LYP hybrid functional with a small basis set such as 6-31g(d) can result in much larger errors as was shown by Bauschlicher and Partridge yielding a mean average error of ca. 5.2 kcal/mol for atomization energies; b) C. W. Bauschlicher Jr, W. A. Goddard III, R. A. Periana, D. M. Heinekey, K. I. Goldberg, W. Leitner et al.
