Zusammenfassung

Die Toll-abhängige dorsoventrale Achsenbildung in *Drosophila* ist eines der am besten verstandenen genregulatorischen Netzwerke. Außerhalb der Insekten ist Toll jedoch nicht für eine achsenbildende Funktion bekannt, sondern für eine Rolle bei der Pathogenabwehr. Bei den meisten anderen Tieren wird die dorsoventrale Achsenbildung durch eine BMP-Signalkaskade induziert. Wie sich die Verschiebung von einer BMP-basierten zu einer Toll-dominierten Form der dorsoventralen Achsenbildung innerhalb der Insektenlinie evolviert hat, ist noch nicht ausreichend erforscht. Frühere Arbeiten haben gezeigt, dass in der Wanze *Oncopeltus fasciatus* Toll nur zur Polarisierung eines dynamischen BMP-Signalkadennetzwerks erforderlich ist, einer Architektur, die den Merkmalen der dorsoventralen Achsenbildung bei Wirbeltieren und anderen Tieren ähnlicher ist als bei jedem anderen bisher untersuchten Insekt.

In dieser Arbeit habe ich ein embryonales Mikroinjektionsprotokoll zur Injektion von Komponenten des Toll- und BMP-Signalwegs entwickelt, um diese Signalkaskaden ektopisch in Wildtyp- und dorsalisierten Toll-Knockdown-Embryonen zu aktivieren, und die induzierten Genexpressionsmuster mittels In-situ-Hybridisierungen analysiert. Zusammen mit phänotypischen Analysen zeigen meine Experimente, dass der Transkriptionsfaktor Snail eine entscheidende Komponente des BMP/Sog-Systems von *Oncopeltus* ist und damit eine Achsenbildungsfunktion hat, die für keinen anderen Organismus beschrieben ist. Ich schlage ein genregulatorisches Netzwerk mit Snail vor, das das bisherige BMP/Sog-System von *Oncopeltus* erweitert und in der Lage ist, das Mesoderm, Ektoderm und Mesectoderm zu induzieren.

Darüber hinaus habe ich Transkriptome von Wildtyp- und RNAi-vermittelten Knockdown-Embryonen erstellt, die auf wichtige dorsoventrale Musterbildungsgene des Toll- und BMP-Signalwegs abzielen. Ich führte RNAseq durch und analysierte eine Untergruppe von unterschiedlich exprimierten Genen durch In-situ-Hybridisierung und RNAi-vermittelte Knockdown-Generation. Mehrere in der Literatur noch nicht beschriebene Expressionsmuster wurden dabei entdeckt, unter anderem für die Serosa, für die es bisher keinen eigenständigen Marker gab.

Abstract

Toll-dependent dorsoventral axis patterning in *Drosophila* represents one of the best understood gene regulatory networks. However, outside the insects Toll is not known for a patterning function, but rather for a role in pathogen defense. In most other animals the dorsoventral axis is patterned by BMP signaling. How the shift from a BMP-based to a Toll-dominated mode of dorsoventral axis patterning within the insect lineage evolved has remained elusive. Previous work has shown that in the milkweed bug *Oncopeltus fasciatus* Toll is only required to polarize a dynamic BMP signaling network, an architecture that resembles characteristics of dorsoventral axis patterning in vertebrates and other animals more than any other insect studied so far.

In this work, I established an embryonic microinjection protocol to inject Toll and BMP pathway components to ectopically activate these pathways in wild-type and dorsalized Toll knockdown embryos and analyzed the induced gene expression patterns via in situ hybridizations. Together with phenotypic analysis my experiments revealed, that the transcription factor Snail is a crucial component of the BMP/Sog system of *Oncopeltus* and thus has an axis patterning function that is not described for any other organism. I propose a gene regulatory network including Snail that extends the previous BMP/Sog system of *Oncopeltus* and is able to pattern the mesoderm, ectoderm and mesectoderm.

In addition, I generated transcriptomes of both wild type and RNAi-mediated knockdown embryos, targeting essential dorsoventral patterning genes of the Toll and BMP pathway. I performed RNAseq and analysed a subset of differentially expressed genes via in situ hybridizations and RNAi-mediated knockdown generation. Several expression patterns were found that have never been described before, including two markers of the serosa, an embryonic fate that lacked a distinct marker in *Oncopeltus* as of yet.

1. Introduction

1.1. The conservation of body axis formation in animals

The number of body plans, shapes and sizes among animals is incredibly diverse, yet in the vast majority of phyla animals possess two major body axes, the anteroposterior (AP) and the dorsoventral (DV) axis. How animals establish and pattern their primary body axis is one of the most fundamental problems in biology. The signaling pathways and gene regulatory networks underpinning axis formation seem to be well conserved among animals. For example, the conservation of positional roles for Hox genes suggests the existence of an AP axis patterning system used by most if not all bilaterally symmetric animals (Slack et al., 1993; Holland, 2013). Data from diverse deuterostomes and from protostomes suggest that Wnt signaling through β -catenin controls posterior identity during AP axis formation in most bilaterally symmetric animals (Petersen and Reddien, 2009). DV axis patterning mechanisms are highly conserved as well and most animals use BMP signaling to pattern their DV axis (Fig. 1) (Little and Mullins, 2006; De Robertis, 2008; Bier, 2011; Bier and De Robertis, 2015). A substantial amount of work is published for the role of BMP signaling in axis patterning of diploblasts [e.g., cnidarians (Genikhovich et al., 2015; Niehrs, 2010)], lophotrochozoa [e.g., planaria (Reddien et al., 2007; Molina et al., 2011; Gaviño et al., 2011) and annelids (Denes et al., 2007; Kuo and Weisblat, 2011)], arthropods [e.g., spiders (Akiyama-Oda and Oda, 2003; Akiyama-Oda and Oda, 2006; Pechmann et al., 2017; Pechmann, 2020)] and deuterostomes [e.g., echinoderms and nonvertebrate chordates like amphioxus (Lapraz et al., 2009; Yu et al., 2007)]. However, in the following I will focus on reviewing the existing knowledge on DV axis patterning of vertebrates and insects as it seems to be most relevant for understanding the DV patterning mechanisms of *Oncopeltus fasciatus*.

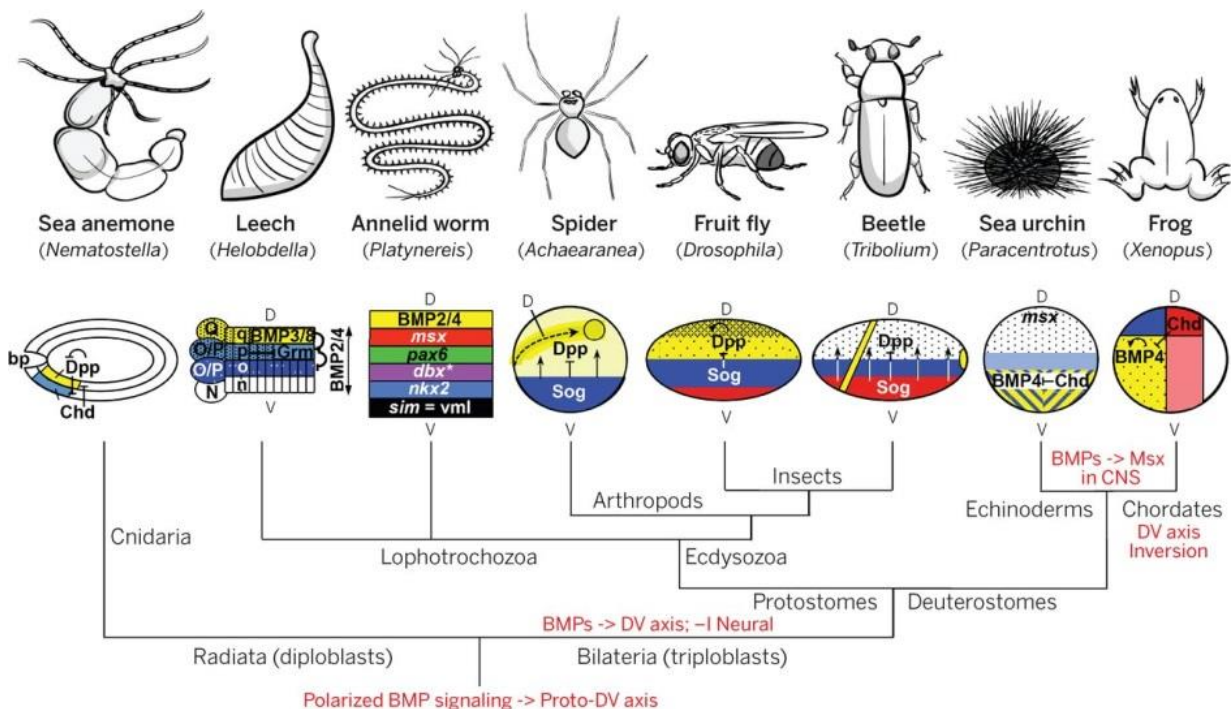

Figure 1: Phylogeny of animals using BMP signaling to pattern body axes

Phylogeny of selected animals in which substantial data for BMP-mediated axes patterning is available. Despite many alterations in expression pattern profiles of BMP signaling components, the developmental outcome of

this signaling pathway has remained conserved across diverse phyla (e.g., suppression of neural fates by BMP signaling). Red text indicates nodes at which specific changes in BMP signaling may have occurred (Figure taken from Bier and De Robertis, 2015).

1.2 Dorsoventral axis establishment in vertebrates

Classic graft manipulation experiments by Spemann and Mangold in which the dorsal blastopore lip of donor newt embryos was transplanted into recipient newt embryos lead to a secondary axis induction (Spemann and Mangold, 1924). Since two different newt species with different degrees of pigmentation were used in these grafting experiments it was possible to distinguish between the mesodermal-derived notochord which developed from donor cells and ectodermal-derived neuronal tube which developed from the host cells within the graft-induced duplicated axis. Hence the transplanted blastopore lip induced neuronal fates in tissues that were originally fated to become epidermis. The dorsal blastopore lip seemingly emitted a neuralizing signal to its surrounding tissue. Spemann later named the dorsal blastopore lip the organizer. Later, various experiments conducted in several vertebrate species revealed that also fish, frog, chick and mouse possess a Spemann organizer-like structure (the shield in zebrafish, node in mouse, and Henson's node in chick) which produced neural-inducing signals. These signals were found to act by inhibiting the bone morphogenetic protein (BMP) pathway. Although there is elaborate research data available for mice and chicken (Coffinier et al., 2002; Moser et al., 2003; Kamimura et al., 2004; Timmer et al., 2002; Wilson and Maden, 2005; Le Dréau and Martí, 2012), BMP-mediated DV patterning in vertebrates is best understood in the African clawed frog *Xenopus laevis* and the zebrafish *Danio rerio*.

BMP ligand genes are expressed in a dynamic manner in the early *Xenopus* embryo (Nishimatsu et al., 1992; Dale et al., 1992; Fainsod et al., 1994; Clement et al., 1995; Hemmati-Brivanlou and Thomsen, 1995; Schmidt et al., 1995; Wang et al., 1997; Fritz and Sheets, 2001). mRNAs encoding *bmp2*, *bmp4*, and *bmp7* are maternally contributed to the egg and are found ubiquitously throughout the early embryo. Maternal *bmp2* transcript is degraded during mid-blastula stage, and *bmp2* is not transcribed zygotically until mid-gastrulation. Zygotic transcription of *bmp7* and *bmp4* is activated at the midblastula transition and both are expressed throughout the embryo, but get degraded dorsally at the early gastrula stage. As gastrulation proceeds, the domain of BMP gene expression is gradually reduced from a broad domain encompassing the ventral and lateral regions to a ventrally-restricted segment near the end of gastrulation. Thus, the early ubiquitous domain of maternal BMP expression becomes restricted zygotically, beginning with a clearing on the dorsal side at midblastula, and gradually moving into more lateral domains as gastrulation proceeds.

A similar pattern of BMP ligand expression is found in zebrafish embryos (Kishimoto et al., 1997; Martinez-Barbera et al., 1997; Nikaido et al., 1997; Dick et al., 2000; Schmid et al., 2000; Furthauer et al., 2004). mRNAs coding for *bmp4* and *bmp7* are found in immature oocytes (Kramer et al., 2002), but are either weakly detected or are absent at the two to four cell stage (Dick et al., 2000). *bmp2b* and *bmp7* are expressed throughout the early blastula and are then cleared from the dorsal side. *bmp4* is expressed ventrally just prior to the onset of gastrulation, so that during gastrulation all three BMP ligands are broadly expressed in the ventral half of the embryo.

BMP signaling itself regulates BMP ligand gene expression in a positive feedback loop, thus ensuring continued BMP activity (Metz et al., 1998). Maternal signaling via Smad5 likely initiates embryo-wide zygotic expression of *bmp2b* and *bmp7* in zebrafish, and *bmp4* and *bmp7* in *Xenopus* (Kramer et al., 2002). Disruption of BMP-mediated positive feedback is essential for the loss of *bmp* expression from

the dorsal side. The initial dorsal clearance of *bmp* expression is mediated by various overlapping mechanisms, involving transcriptional repression dependent on the homeodomain protein Bozozok, β -catenin, Wnt and FGF signaling, as well as MAP Kinases, which leads to the establishment of broad BMP-positive and BMP-negative regions demarcating initial dorsal and ventral domains in the late blastula stage embryo (Lemaire et al., 1995; Furthauer et al., 1997; Kretzschmar et al., 1997; Baker et al., 1999; Koos and Ho, 1999; Fekany-Lee et al., 2000; Gomez-Skarmeta et al., 2001; Furthauer et al., 2001; Lekven et al., 2001; Leung et al., 2003; Pera et al., 2003; Furthauer et al., 2004; Tsang et al., 2004; Ramel and Lekven, 2004; Stern, 2005; Kuroda et al., 2005; Ramel et al., 2005).

However, these mechanisms of transcriptional BMP ligand repression acting on the dorsal domain do not explain the classic observations of Spemann and Mangold that transplanted dorsal organizer tissue can redirect the development of ventral host tissue to take on dorsal fates. In addition, supplying BMP ligand mRNA ubiquitously throughout a zebrafish embryo can rescue *bmp2b* and *bmp7* mutants to wild-type, indicating that additional mechanisms must regulate DV axis patterning (Kishimoto et al., 1997; Nguyen et al., 1998). Moreover, the broad ventral expression of BMP ligand genes does not explain how BMP signaling acts in a graded fashion along the DV axis.

These properties are mediated by dorsal organizer-derived BMP signaling antagonists. Two such antagonists are Chordin (Chd) and Noggin (Nog) which are secreted by and produced within the organizer at the start of gastrulation (Sasai et al., 1994; Smith and Harland, 1992). Those inhibitors can induce dorsal fates in ectoderm and mesoderm in a dose-dependent manner and produce a secondary axis when ectopically expressed ventrally, thus mimicking the activity of organizer tissue (Dosch et al., 1997; Wilson et al., 1997; Bauer et al., 1998; Eimon and Harland, 1999; Furthauer et al., 1999). Chordin and Noggin themselves do not directly specify cell fates, but instead block BMP signaling by directly binding BMP ligands extracellularly and BMP ligands bound to these antagonists cannot interact with receptors and thus cannot signal (Smith and Harland, 1992; Sasai et al., 1994; Piccolo et al., 1996; Zimmerman et al., 1996). *chordin* expression extends outside the organizer into future neural tissue in both *Xenopus* and zebrafish, as well as into marginal dorsolateral regions well outside the organizer in zebrafish (Schulte-Merker et al., 1997; Miller-Bertoglio et al., 1997; Kuroda et al., 2004). Zebrafish embryos that lack Chordin display reduced neural plate, reduced paraxial tissue, and slight reduction of the dorsal-most axial mesoderm, with expansion of ventral fates, indicating excess BMP signaling (Hammerschmidt et al., 1996; Oelgeschlager et al., 2003). Lack of Chordin also attenuates the ability of the organizer to induce a secondary axis in transplant experiments (Oelgeschlager et al., 2003). However, overexpression of *chordin* induces dorsal fates in a dose-dependent manner, and this can occur at a distance from the site of *chordin* expression (Jones and Smith, 1998; Blitz et al., 2000). The restricted expression of *chordin* and *noggin* on the dorsal side, combined with the broad expression of BMP ligands ventrally, has led to a model in which BMP antagonists diffuse laterally from their sites of expression (Thomsen, 1997). The ventrally-directed movement of Chordin and Noggin causes a DV gradient of anti-BMP activity, resulting in an inverse gradient of BMP activity with high levels ventrally and decreasing levels in progressively more lateral regions. Thus, the movement of BMP antagonists from dorsal to ventral sets up a BMP activity gradient, which establishes differential cell fates in an activity-level dependent manner. An antibody which specifically detects phosphorylated Smads, the effectors of vertebrate BMP signaling, reveals high levels of pSmad ventrally and no staining near the organizer, consistent with the proposed gradient (Faure et al., 2000; Mintzer et al., 2001; Schohl and Fagotto, 2002).

Extracellular antagonism of BMP signaling is indispensable for DV patterning. The triple depletion of Chordin, Noggin, and Follistatin, another extracellular BMP antagonist (Hemmati-Brivanlou et al., 1994), causes a complete loss of neural tissue and dorsal mesoderm in *Xenopus*, demonstrating a

certain degree of redundancy between the extracellular antagonists. The establishment of the organizer is not affected by this triple antagonist knockdown, however, the dorsalizing activities of β -catenin signaling are not sufficient to maintain any dorsal identity if BMP antagonists are absent (Khokha et al., 2005). In zebrafish, lack of Chordin and the transcriptional repressor Bozozok massively derepress BMP expression and lead to radialized ventral fates (Gonzalez et al., 2000). Thus, both extracellular antagonists and transcriptional repression are required to repress ventralizing BMP signals to allow dorsal development.

Many additional factors influence BMP signaling at the extracellular level. Among them are members of the Tolloid family, that promote BMP signaling via inactivation and degradation of Chordin. Multiple homologs of the metalloprotease Tolloid are found in vertebrates (Ge and Greenspan, 2006). The first vertebrate Tolloid-related protease identified, BMP1, was purified along with BMP ligands from demineralized bone extracts (Wozney et al., 1988). BMP1 homologs have been identified in fish, frog, mouse, and human. Additional related genes are, in *Xenopus*, *Xolloid* (*Xld*) and *Xolloid-related* (*Xlr*) (Goodman et al., 1998; Dale et al., 2002), and in zebrafish, *tolloid-like 1* (*tll1*), *bmp1a*, and *bmp1b* (Blader et al., 1997; Muraoka et al., 2006). Of these factors, those studied most intensely for their role in DV patterning have been, in frog, *Xld* and *Xlr*, and in zebrafish, *bmp1a* and *tll1* (Connors et al., 1999). These genes are members of the “BMP synexpression group” of genes that are expressed ventrally and are positively regulated by BMP signaling (Karaulanov et al., 2004). The anti-Chordin activity of Tolloid can be interpreted as sink for Chordin by which the diffusing BMP antagonist can be destroyed, thus maintaining a gradient of BMP activity.

1.3 Dorsoventral axis establishment in *Drosophila melanogaster*

While most animals employ BMP signaling to pattern their DV axis, extensive amounts of research since the 1970s revealed that in the fly *Drosophila* the Toll signaling pathway gained dominance over BMP signaling in DV axis establishment (Stein and Stevens, 2014; Sachs et al., 2015). In *Drosophila* BMP signaling also plays a crucial, but spatially restricted role in patterning the most dorsal fates, in particular the amniosera and the dorsal ectoderm (O'Connor et al., 2006).

This is somehow surprising since Toll signaling itself is a highly conserved pathway from Hydra to human, providing innate immunity (Lemaitre et al., 1996; Leulier and Lemaitre, 2008; Franzenburg et al., 2012; Gilmore and Wolenski, 2012).

Genetic screens carried out largely in the 1970s and 1980s identified a group of genes collectively referred to as the dorsal group (Nüsslein-Volhard, 1979; Nüsslein-Volhard et al., 1980; Anderson and Nüsslein-Volhard, 1984a; Anderson and Nüsslein-Volhard, 1984b; Nüsslein-Volhard et al., 1987; Schüpbach and Wieschaus, 1989; Luschnig et al., 2004). Among this group is a ubiquitously expressed gene called *Toll*, which codes for a leucine-rich repeat-bearing single-pass transmembrane receptor (Hashimoto et al., 1988). Toll is uniformly distributed throughout the plasma membrane of the syncytial blastoderm stage embryo (Hashimoto et al., 1991). The molecular events which occur up and downstream of the Toll receptor are known in great detail (Fig. 2).

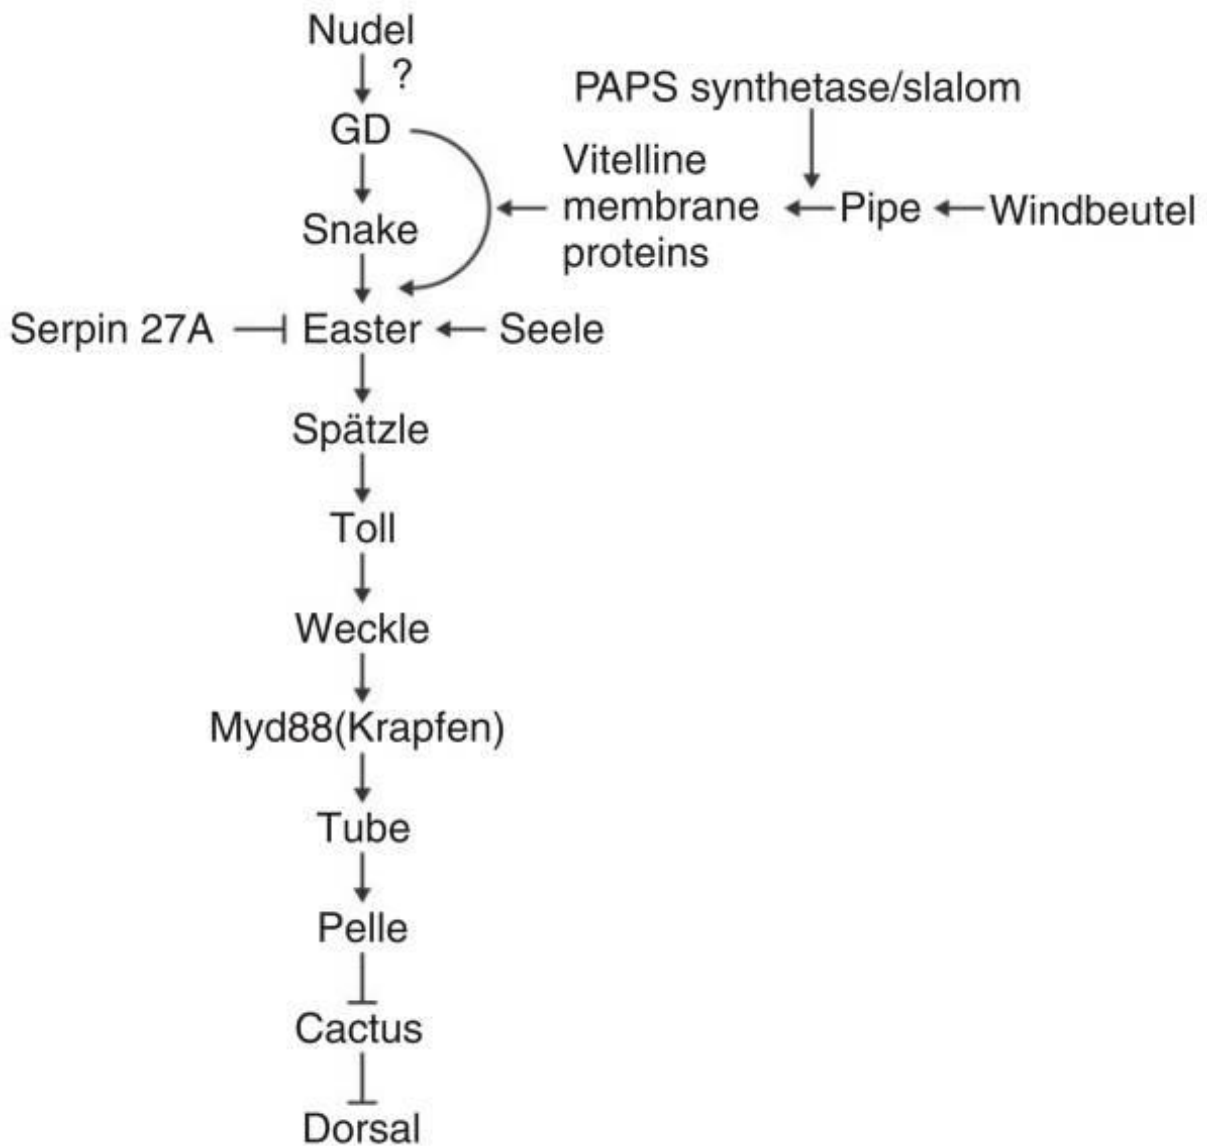

Figure 2: Components of the Toll signaling pathway

Overview of the gene products known to be involved in dorsoventral patterning of the *Drosophila* embryo in their order of action and epistatic relationship (Figure taken from Stein and Stevens, 2014).

Upstream of the Toll receptor, within the perivitelline space between the eggshell and the embryonic membrane, acts a protease cascade that processes the ligand of the Toll receptor into its active form. The activity of the protease cascade is restricted to the ventral side of developing embryos. The mechanisms that establish this ventral activity restriction are known in great detail (Fig. 3).

In order to achieve the ventral activity restriction of proteolytic events upstream of Toll during embryo development, a molecular cue in the egg that transmits spatial information is already established in the oocyte (Schüpbach, 1987). During oogenesis, *gurken* mRNA, coding for an TGF- α -like secreted peptide growth factor, is expressed by the nurse cells and then transported into the oocyte (Neuman-Silberberg and Schüpbach, 1993). At stage 8, the oocyte nucleus has migrated from its original position at the posterior of the oocyte to an anterior position adjacent to the oocyte/nurse cell boundary and *gurken* mRNA localizes in association with the oocyte nucleus (Neuman-Silberberg and Schüpbach, 1996; Saunders and Cohen, 1999; Thio et al., 2000; Caceres and

Nilson, 2005). Gurken protein is synthesized within and secreted from this corner of the oocyte, and subsequently activates Torpedo in the overlying follicle cells, defining the dorsal side of the follicular epithelium (Neuman-Silberberg and Schüpbach, 1996; Peri et al., 1999; Bökel et al., 2006; Castro et al., 2007). Torpedo is the *Drosophila* homologue of the Epidermal Growth Factor Receptor (Price et al., 1989; Schejter et al., 1989). Activation of Torpedo results in the phosphorylation and inactivation of Capicua, a HMG-Box protein that acts as repressor of *mirror* (Astigarraga et al., 2007; Atkey et al., 2006; Goff et al., 2001). Torpedo signaling-mediated inactivation of Capicua in dorsal and lateral follicle cells leads to the expression of the transcription factor encoding gene *mirror*, which in turn represses *pipe* transcription (Andreu et al., 2012). However, in ventral follicle cells Capicua represses *mirror* and *pipe* is expressed (Andreu et al., 2012, Atkey et al., 2006; Goff et al., 2001).

Figure 3: EGFR signaling ventrally restricts expression of *pipe* in the follicle cell layer during oogenesis
 Schematic drawing of a stage 10 oocyte. *pipe* is expressed in the ventrally (blue), but repressed in the dorsal epithelium (green). Relevant effector peptides and their activation states in ventral and dorsal follicle cells are indicated at right (Figure taken from Stein and Stevens, 2014).

pipe codes for a sulfate 2-O-sulfotransferase that exhibits a type II transmembrane topology, consistent with its localization to the Golgi apparatus (Sen et al., 1998; Kobayashi et al., 1997; Kobayashi et al., 1999). Golgi localization of Pipe requires chaperone activity of Windbeutel, a dorsal group protein and *Drosophila* homologue of the vertebrate chaperone ERp29 (Sen et al., 2000; Konsolaki et al., 1998). The question of the substrate of Pipe remains controversial (Park et al., 2008; Zhu et al., 2005). However, despite the uncertainty about Pipes target carbohydrate, there is strong evidence that Pipe-associated sulfotransferase activity is necessary for the formation of embryonic DV polarity as hypomorphic *pipe* mutations lead to weak dorsalization that can be enhanced by feeding mutant female flies an inhibitor of the enzyme PAPS synthetase (Anderson and Nüsslein-Volhard, 1984; Zhu et al., 2005). PAPS is a cosubstrate and source of activated sulfate for sulfotransferases (Robbins and Lipmann, 1957; Kobayashi et al., 1996; Kobayashi et al., 1999). In addition, female flies bearing follicle cell clones lacking the function of either PAPS Synthetase or Slalom, a transporter of PAPS from the cytoplasm to the Golgi produce dorsalized progeny embryos (Zhu et al., 2007; Lüders et al., 2003; Kamiyama et al., 2003). Thus, Pipe-mediated sulfation in the follicular epithelium is required for the establishment of the DV axis in *Drosophila* embryos.

A protein target of Pipe sulfotransferase activity is the Vitelline Membrane-Like (VML) protein (Zhang et al., 2009). Sulfated VML is secreted by the follicle cells and becomes stably associated with the region of the vitelline membrane that lies adjacent to the site of *Vml* expression in the follicular epithelium (Zhang et al., 2009; Alartortsev, 2006; Scherer et al., 1988). Other vitelline membrane associated proteins that undergo Pipe-dependent sulfation have been identified (Zhang et al., 2009; Burke et al., 1987; Popodi et al., 1988; Gigliotti et al., 1989; Elalayli et al., 2008). Embryos from mothers homozygous for a mutation that eliminates VML or other vitelline membrane associated proteins are not dorsalized. However, the hypomorphic *pipe* phenotype is enhanced by a reduction in the gene dosage of VML or the other vitelline membrane associated proteins sulfated by Pipe suggesting that these other Pipe substrates act redundantly with VML to influence Toll signaling (Zhang et al., 2009). In summary, it is thought that VML and other glycosylated vitelline membrane components are sulfated by Pipe and then secreted and incorporated into the vitelline membrane, where they comprise a ventrally localized cue that restricts the activity of the protease cascade that processes the Toll ligand.

It has been shown experimentally that GD, a member of the protease cascade upstream of Toll interacts with Pipe-sulfated molecules that are embedded in the ventral vitelline membrane and thereby accumulates on the ventral side of developing *Drosophila* embryos (Cho et al., 2012). In addition, processing of the Easter zymogen, another member of the protease cascade, requires Pipe activity (Cho et al., 2010; LeMosy, 2006; Steen et al., 2010).

In summary, DV polarity of the embryo is dependent upon prior DV polarity establishment within the follicle cell layer surrounding the oocyte. In this process Pipe is a central component that links EGFR-mediated DV polarity from the egg chamber to Toll-mediated DV polarity of the embryo by providing a spatial cue that restricts Toll activity to the ventral side.

Figure 4: Sulfation of VML by Pipe in a ventral follicle cell

PAPS is transported into the Golgi apparatus by Slalom. Pipe present in the Golgi apparatus transfers sulfate from PAPS to VML. Sulfated VML is then secreted and incorporated into the vitelline membrane layer of the egg (Figure taken from Stein and Stevens, 2014).

The protease cascade upstream of Toll consists of three distinct serine proteases, Gd, Snake and Easter. The presence of signal peptides in GD, Snake and Easter suggested that they are secreted from the embryo and function within the perivitelline fluid that surrounds the developing embryo (Stein and Stevens, 2014). Both *snake* and *easter* are expressed in the germline and code for trypsin-like serine proteases (DeLotto and Spierer, 1986; Chasan and Anderson, 1989). They are expressed as inactive zymogens and are both activated by a cleavage reaction that cuts the backbone of the protein between an N-terminal segment, the prodomain, and the catalytic region in the C-terminus. Although the proteolytic function of Easter and Snake is activated by the cleavage event, the prodomain and catalytic fragments remain linked by a disulfide bond. The prodomains of both Snake and Easter carry six cysteine residues that are predicted to form three intra-chain disulfide bridges that form a structure termed Clip domain because of its resemblance to a paper clip (Muta et al, 1990; Smith and DeLotto, 1992; Jiang and Kanost, 2000). The Clip domain was first found in the proclotting enzyme of the horseshoe crab, *Tachypleus tridentus* (Muta et al, 1990). The Horseshoe crab proclotting enzyme functions in the hemolymph coagulation system and is considered to be the counterpart of prothrombin in the mammalian blood clotting reaction (Miyata et al., 1983). The Clip domain is thought to function as a recognition site for activators or other components of the hemolymph clotting system (Muta et al, 1990; Smith and DeLotto). *gd* also codes for a protease, but rather than a trypsin-type protease, GD instead exhibits limited structural similarity to two serine proteases of the mammalian complement system, factors C2 and B (Konrad et al., 1998; DeLotto, 2001). *gd* is both expressed in the germline and follicle cells where accumulation of mRNA appears to be somewhat graded along the dorsal–ventral axis with marginally higher levels of mRNA in the ventral follicle cells (Konrad et al., 1998).

Various genetic and biochemical experiments revealed the epistatic relationships within the proteolytic cascade upstream of Toll and support a model in which GD acts on Snake, Snake on Easter, and Easter cleaves and thereby activates Spätzle, the ligand for Toll (Chasan et al., 1992; Smith and DeLotto, 1995; Dissing et al., 2001; LeMosy et al., 2001; Stein and Nüsslein-Volhard, 1992). Spätzle is a neurotrophin-like signaling peptid and the C-terminus of Easter-processed Spätzle forms a disulfide-linked homodimer that acts as active Toll ligand (Stein et al., 1991; Morisato and Anderson, 1994; Schneider et al., 1994; Weber et al., 2003; Lemaitre et al., 1996; DeLotto and DeLotto, 1998).

Besides proteolytic activation by Snake, Easter activity is regulated by various mechanisms. Processed Easter is rapidly bound and inactivated by the inhibitor Serpin 27A. *serpin 27A* mRNA is maternally provided and Serpin 27A is uniformly distributed along the DV axis, thereby preventing activated Easter from diffusing to lateral and dorsal regions (Misra et al., 1998; Ligoxygakis et al., 2003; Hashimoto et al., 2003). Easter is also regulated at the level of secretion by Seele, an endoplasmic reticulum-localized saposin-like protein. In embryos lacking Seele the secretion of Easter, but not of other secreted dorsal group proteins, is disrupted, leading to a weakly dorsalized embryonic phenotype (Stein et al., 2010). Hence, Easter can be seen as a critical control point for regulation of Toll pathway activity.

Figure 5: Processing of Spätzle by a ventrally active protease cascade

The Spätzle ligand is processed within the ventral perivitelline space. VML-associated and free GD processes and thereby activates Snake. Only GD which is associated with Pipe-sulfated VML promotes the interaction between activated Snake and unprocessed Easter zymogen, which leads to Easter cleavage and activation. Activated Easter then processes Spätzle into the active Toll ligand. Active Easter is bound and inactivated by Serpin 27A (Figure taken from Stein and Stevens, 2014).

The signaling cascade events downstream of Toll are also known in detail (Fig. 5). Binding of activated Spätzle ligand to Toll induces dimerization of the receptor. Active Toll simultaneously recruits the adaptor proteins Myd88 and Weckle to form a stable complex with Tube that activates Pelle (Towb et al., 1998; Grosshans et al., 1994; Galindo et al., 1995; Sun et al., 2004; Charatsi et al., 2003; Chen et al., 2006). The formation of this complex transmits signaling that is dependent upon the Pelle kinase. Pelle phosphorylates Toll, Tube, Cactus, Dorsal and itself (Reach et al., 1996; Fernandez et al., 2001; Grosshans et al., 1994; Shen and Manley, 1998; Towb et al., 2001; Shen and Manley, 2002; Daigneault et al., 2013). The phosphorylation, ubiquitination and subsequent degradation of Cactus, a *Drosophila* homologue of vertebrate I κ B proteins that regulate NF κ B activity, leads to nuclear uptake of Dorsal, a *Drosophila* homologue of vertebrate Rel and NF κ B proteins (Steward et al., 1987; Bours et al., 1990; Ghosh 1990; Kieran et al., 1990; Nolan et al., 1991; Ruben et al., 1991; Hayden and Ghosh, 2012). In the absence of active Toll signaling Cactus acts as repressor by sequestering Dorsal within the cytoplasm and therefore inhibiting Dorsal from entering the nucleus (Roth et al., 1991; Geiseler et al., 1992; Kidd, 1992; Belvin et al., 1995; Bergmann et al., 1996; Reach et al., 1996).

Figure 6: Toll activation and signaling leads to nuclear uptake of Dorsal

Binding of activated Spätzle to Toll leads to the Weckle-dependent recruitment of a complex comprised of Myd88, Tube, and Pelle. Toll activation leads to the phosphorylation, ubiquitination and degradation of Cactus, releasing Dorsal to enter the nucleus (Figure taken from Stein and Stevens, 2014).

The outcome of ventrally active Toll signaling establishes a gradient of nuclear Dorsal exhibiting peak levels at the ventral-most side, intermediate levels at the lateral sides and low levels on the dorsal-most side (Rushlow et al., 1989; Steward, 1989; Roth et al., 1989; Liberman et al., 2009; Reeves et al., 2012; Reeves and Stathopoulos, 2009; DeLotto et al., 2007) (Fig. 7). A complete understanding of the formation of the Dorsal nuclear gradient is still a work in progress, however, the current understanding suggests an extracellular Spätzle gradient that results in graded Toll activity (Stein and Stevens, 2014). As nuclei enter mitotic prophase, the gradient disappears, then reappears at the end

of mitosis and the gradient must re-form multiple times during the nuclear division cycles 10 through 14 (DeLotto et al., 2007; Kanodia et al., 2009).

The nuclear concentration of Dorsal along the embryonic DV axis defines the transcriptional state of Dorsal target genes in a threshold-dependent manner (Roth et al., 1989; Stathopoulos and Levine, 2002; Reeves and Stathopoulos, 2009) (Fig. 7). Type 1 target genes like *twist* and *snail* bear low affinity binding sites for Dorsal and are activated only in cells containing high levels of Dorsal, which will form ventral mesoderm. Type 2 target genes, such as *rhomboid*, *vnd*, and *brinker*, bear high affinity binding sites for Dorsal and are expressed in the ventral domain of the neurogenic ectoderm, where nuclear Dorsal is present at intermediate levels (Jiang and Levine 1993; Papatsenko and Levine 2005).

Beside the affinity and number of Dorsal binding sites, the boundaries of Dorsal target genes are defined by binding sites for additional transcription factors. For example the regulatory regions of the type 2 target *rhomboid* contain both binding sites for Dorsal and Twist, Daughterless, Scute and Su(H), which all co-activate *rhomboid*, while Snail represses (Bier et al., 1990; Ip et al., 1992; Jiang and Levine, 1993; Markstein et al., 2004).

Gene expression in dorsolateral regions of the embryos (Type 3+, e.g. *sog*) requires the function of both Dorsal and Zelda, while in dorsal regions (Type 3-, e.g. *zen*, *dpp* and *tld*), Dorsal activity must be essentially absent but Zelda is still required (Liang et al., 2008; Liberman and Stathopoulos 2009).

Dorsal's intrinsic activity is to turn on gene expression, but Dorsal can function as repressor for type 3- targets by facilitating the binding of co-repressor proteins to neighboring AT-rich regions within the Ventral Repression Elements (VREs) of *zen*, *tld* and *dpp* (Kirov et al., 1993; Huang et al., 1993; Jiang et al., 1993; Kirov et al., 1994; Lehming et al., 1994; Huang et al., 1995; Cai et al., 1996; Valentine et al., 1998).

While it seems that only three distinct Dorsal-mediated activation thresholds exist, up to six different gene-expression patterns have been identified that are generated by additional activators or repressors downstream of Dorsal. Besides the already described patterns two additional gene expression patterns, Type 1A (e.g. *sim*) and Type2A (e.g. *ind*), have been described, that in addition to Dorsal involve Notch or EGF signalling, respectively (Hong et al., 2008).

Figure 7: Dorsal target genes and their threshold levels

(A) Cross section of Stage 5 *Drosophila* embryo, stained with an α -Dorsal antibody. **(B)** Cross section of Stage 5 *Drosophila* embryo, stained by ISH to detect the Dorsal target gene transcripts *dpp*, *ind*, *vnd*, *sog* and *sna*. **(C)** Dorsal and Twist cooperate to specify Type I and Type II Dorsal target genes. Dorsal functions together with Zelda to support expression of Type III target genes. **(D)** Fate map schematic. The nuclear Dorsal gradient divides the embryo into three main subtissues: mesoderm, neurogenic ectoderm, and dorsal ectoderm. The neurogenic ectoderm can be divided into ventral and dorsal halves. **(E)** Groupings of Dorsal target gene

thresholds. Type I genes are expressed in the ventral-most cells of the embryo, where Dorsal nuclear levels are the highest. Type II genes have dorsal borders in the middle of the neurogenic ectoderm and are repressed by Snail. Type III genes have their dorsal (+) or ventral (-) borders at roughly 50% DV axis, and contain sites for both Dorsal binding as well as a Zelda, a uniformly expressed activator (Figure taken from Reeves and Stathopoulos, 2009).

1.4 Dorsoventral axis establishment in *Oncopeltus fasciatus* and other insects

The early embryonic development of *Drosophila* displays many derived features compared to other insects. The beetle *Tribolium castaneum* exhibits a more representative mode of embryogenesis for insects in general (Brown et al., 2009). In *Tribolium* Toll signaling is also essential for mesoderm specification and polarization of BMP signaling. However, in contrast to *Drosophila* Toll signaling is only weakly polarized by maternal cues in *Tribolium*. Instead, Toll gradient formation in *Tribolium* is dynamic and depends on extensive zygotic feedback mechanisms (Nunes da Fonseca et al., 2008). The Toll gradient in *Tribolium* provides less spatial information for direct target gene control compared to *Drosophila* (Chen et al., 2000). Accordingly, the number of Toll target genes is smaller than in *Drosophila* (Stappert et al., 2016). Among the BMP signaling components of *Tribolium* only *sog* has been identified as direct Toll target (van der Zee et al., 2006).

In the jewel wasp *Nasonia vitripennis*, a representative of Hymenoptera, the most basal branching line within the Holometabola (insects with complete metamorphosis) Toll's role in DV patterning is even less pronounced (El-Sherif et al., 2012; Schmidt-Ott and Lynch, 2016). In *Nasonia*, Toll signaling seems to be active only in a narrow domain of cells along the ventral midline (Buchta et al., 2013; Özüak et al., 2014b). In this domain Toll initiates mesoderm specification, but does not determine the final size of the mesodermal region which depends on inhibition by BMP signaling. Like in other insects, BMP also specifies the cell fates of the dorsal half of the *Nasonia* embryo, and therefore provides patterning information along the entire DV axis. In addition, BMP gradient formation in *Nasonia* is independent of Toll and possesses its own maternal source along the dorsal midline (Özüak et al., 2014a). Thus, DV axis patterning in *Nasonia* is dominated by BMP signaling while Toll's function is reduced to being a local inducer instead of a long-range morphogen.

A common feature of all holometabolous insects studied so far is the strict reliance on Toll signaling for mesoderm specification.

However, in the milkweed bug *Oncopeltus fasciatus* (Hemiptera), a representative of the Hemimetabola (insects with incomplete metamorphosis) Toll signaling is only employed as a polarity cue for a self-organizing system of BMP signaling components (Sachs et al., 2015). In *Oncopeltus* Toll signaling never refines to form a steep long-range gradient like in *Drosophila* and *Tribolium* or a pattern of local activation like in *Nasonia*. Instead, Toll rather provides a weak activating function for the BMP inhibitor *sog*. Since in *Oncopeltus* BMP signaling itself represses *sog* transcription a self-regulatory double-negative feedback loop is established which leads to a stable long-range pattern of BMP signaling. As a consequence, all cell fates along the DV axis depend on BMP signaling. The presumptive mesoderm is entirely defined by BMP repression and does no longer require an additional input from Toll (Sachs et al., 2015).

Thus, the *Oncopeltus* BMP system might have preserved regulatory features of an ancestral BMP-based mechanism of DV axis formation more similar to vertebrates like *Xenopus* and zebrafish than to *Drosophila*.

Figure 8: Toll's role in DV patterning across different insects

In holometabolous insects Toll signaling is ventrally activated and forms an activity gradient (red) that is essential at the very least for specifying the ventral-most cells on the DV axis, giving rise to the mesoderm (brown), by activating the gene *twist*. In *Drosophila* Toll signaling not only determines the mesoderm, but also the neuroectoderm (yellow) and restricts BMP signaling to the dorsal side through several parallel mechanisms, including the activation of the BMP inhibitor short gastrulation (*sog*) and repression of the major BMP ligand decapentaplegic (*dpp*). On the dorsal side a BMP gradient (blue) is established that specifies non-neurogenic ectoderm (blue) and extraembryonic tissues (green). In *Tribolium* Toll signaling is dynamic and polarizes BMP signaling only by activating *sog*. BMP signaling in turn has an increased role in ectodermal patterning compared to flies. In contrast to *Drosophila* and *Tribolium* Toll signaling in the wasp *Nasonia* appears to be restricted to a narrow ventral domain where it is only transiently active. In this domain Toll signaling is required to induce mesodermal and mesectodermal fates. But the size of the mesodermal region as well as the fate and position of all other regions along the DV axis are determined by a BMP signaling gradient originating from the dorsal side by an unknown Toll-independent mechanism. Thus, in holometabolous insects BMP signaling gets increasingly more important towards basally branching groups, whereas Toll's role is decreased, but remains essential for ventral-most cell fates. *Oncopeltus* uses Toll signaling only as spatial cue to polarize a dynamic BMP signaling network that establishes a gradient responsible for patterning all cell fates along the entire DV axis. The key regulatory element of this network is the transcriptional repression of *sog* by BMP signaling in a double-negative feedback (Figure taken from Sachs et al., 2015).

1.5 Aim of the study

Sachs et al. provides a theoretical framework for DV axis patterning in *Oncopeltus*, based on phenotypic analysis of core components of BMP and Toll signaling and theoretic modeling approaches (Sachs et al., 2015). The authors propose a system with self-regulatory properties in which the entire DV axis is patterned by a double negative feedback loop comprised of BMP signaling and Sog inhibiting each other. In this system the initial symmetry is broken by ventrally active Toll signaling that only acts as a local inducer of *sog* expression.

To test this hypothesis this study presents experiments in which an ectopic source of BMP inhibition is introduced into both wild-type and embryos lacking Toll via microinjection of the *sog* homolog *chordin*. To examine the injection-induced effects on the DV patterning network different markers were used in ISH experiments. Similar simulations of microinjection experiments were executed within the theoretical model to compare the *in vitro* with the *in silico* data. Additionally, differential expression analysis by RNAseq of distinct phenotypic transcriptomes of Toll and BMP signalling core components was performed in order to discover new marker genes of embryonic fates and potentially novel components of axis patterning.

2. Materials and Methods

2.1 Materials

2.1.1 Chemicals

Chemicals were purchased from Ambion, BAUER, Merck, PFALTZ, Roche, Roth, Sigma and VWR. Chemicals ordered from other companies were marked as such.

2.1.2 Reagent Kit

Table 1: Reagent Kits used during experiments

Reagent Kit	Company
QUIAGEN Plasmid Miniprep Kit	Quiagen
TOPO™ TA Cloning™ Kit (pCR™II TOPO® TA vector)	Invitrogen
SuperScript® VILO™ cDNA Synthesis Kit	Life Technologies
MEGAscript® KIT	Ambion
MAXIsript™ T7 Transcription Kit	Ambion
High-Fidelity PCR Kit	Invitrogen
5x MEGAscript T7 Kit	Invitrogen
mMessage mMachine™ SP6	Invitrogen
Advantage® 2 PCR Kit	Clontech
ZR Plasmid Miniprep Classic	Zymo Research
mMessage mMachine® T7 Kit	Ambion
mMessage mMachine® SP6 Kit	Ambion

2.1.3 Solutions and Buffers

Applied water was purified by double filtration and autoclaved afterwards. If necessary, the pH was adjusted with HCl or NaOH.

For general use:

Phosphate buffered saline (PBS), 1 x

NaCl	137 mM
KCl	2.7 M
NaHPO ₄	8 mM
KH ₂ PO ₄	1.7 mM

Phosphate buffered saline with Tween-20 (PBST), 1 x

NaCl	137 mM
------	--------

KCl	2.7 M
NaHPO ₄	8 mM
KH ₂ PO ₄	1.7 mM
Tween-20	0.1 %

Sodium Dodecyl Sulfate (SDS), 10 %

C ₁₂ H ₂₅ SO ₄ Na	10 %
--	------

Saline sodium citrate (SSC), 20 x, pH 5

NaCl	3 M
Na ₃ C ₆ H ₅ O ₇	300 mM

Injection buffer

KCl	5 mM
Na ₂ HPO ₄	0.1 mM

Tris-acetate-EDTA buffer (TAE)

Tris	40 mM
acetic acid	20 mM
EDTA	1 mM

Lysogeny broth (LB) medium, pH 7

yeast extract	0.5 %
NaCl	1 %
tryptone	1 %

Super-optimal broth with catabolite repression (SOC) medium

bacto-tryptone	2 %
bacto-yeast extract	0.5 %
NaCl	10 mM
KCl	2.5 mM
MgCl ₂	10 mM
glucose	20 mM

Fuchsin staining solution:

Alcoholic fuchsin staining solution

Pararosaniline	5 mg/ml
Ethanol	80 %
store at room temperature	

Solution C

Ethanol	50 %
Solution D/BBBA	50 %

Solution D/BBBA

Benzyl benzoate	80 %
Benzyl alcohol	20 %

In situ Hybridization and antibody staining solutions:

Hybridization buffer

Formamide	50 %
SSC, pH	5 5 x
Heparin	100 µg/ml
salmon sperm DNA (ssDNA)	100 µg/ml
transfer-RNA (tRNA)	100 µg/ml
SDS	1 %
Tween-20	0.1 %

Blocking solution

PBS	1 x
Bovine serum albumin (BSA)	2 mg/ml
Goat serum	5 %
Tween-20	0.1 %

Alkaline phosphatase (AP) buffer, pH 9.5

Tris, pH 9.5	0.1 M
MgCl ₂	50 mM
NaCl	100 mM
Tween-20	0.05 %

Probe resuspension buffer

Formamide	50 %
SSC, pH 5	2 x

2.1.4 Oligonucleotides

All oligonucleotides were purchased from Sigma-Aldrich. Primers were designed using the online browser-based version of Primer3web, version 4.1.0 (<https://primer3.ut.ee/>) (Rozen and Skaletsky, 2000).

The Gene ID indicates the gene name or OFAS-number of the official *Oncopeltus fasciatus* gene set (Panfilio et al., 2019). F and R stand for forward and reverse, respectively. The last number indicates the fragment length in nucleotides that is amplified by a pair of primers. Adapters like the T7 adapter sequence are written in lower case letters.

2.2 Methods

2.2.1 Culturing and husbandry of *Oncopeltus fasciatus*

Oncopeltus fasciatus was cultured at 25 °C, fed with sunflower seeds and supplied with tap water-filled erlenmeyer flask that were plugged with paper towels to enable the bugs to drink and prevent them from drowning. Small petri dishes with cotton were supplied in which the females laid their eggs. Detailed husbandry conditions for *O. fasciatus* are described in Liu and Kaufmann, 2009.

2.2.2 Embryo fixation

The embryo fixation protocol for *O. fasciatus* is adapted from Liu and Kaufman, 2004. The space between the chorion and the embryo of *O. fasciatus* is under relatively high pressure. Initially the eggs were heat-fixed to prevent the embryo from being damaged during the eggshell cracking process. Therefore the eggs were transferred into screw top tubes and covered with 1.2 ml distilled H₂O. The tubes were submerged into boiling water for 90 seconds. Afterwards the tubes were immediately cooled down in ice water for 5 minutes. Subsequently the eggs were vortexed in 600 µl heptane and 600 µl 1x PBS with 5 % formaldehyde for 5 minutes. The lower aqueous phase was removed, 600 µl ice cold methanol (-20 °C) were added and the tube was shaken vigorously for 1 minute. Afterwards all liquid was removed and the embryos were again shaken vigorously in 1.2 ml of ice cold methanol. The addition of methanol in combination with vigorously shaking initiated the cracking of the chorion. The embryos were fixed in 1x PBS with 5 % formaldehyde for at least 2 hours. The fixation works via a nucleophile attack of primary amino functional groups, which are mainly found in lysine side chains, to carbonyl functional groups of formaldehyde. This leads to hemiaminals that condensate with further amino functional groups. Thus the proteins become connected to each other. The fixed embryos were stored in methanol at -20 °C.

2.2.3 RNA extraction

Wild-type or knockdown embryos were transferred into a 1.5 ml tube and homogenized with a micro pestle (Eppendorf) in 100 µl TRIzol (Ambion). 900 µl TRIzol were added and the tube was briefly vortexed. Following homogenization the sample was centrifuged at 12000 x *g* for 10 minutes at 4 °C. The cleared supernatant was transferred into a new tube, while solid components were discarded. In TRIzol homogenized embryos could be optionally stored at -80 °C. The homogenized sample was

incubated for 5 minutes at room temperature. 200 μ l chloroform were added and the tube was vortexed for 15 seconds. After incubation at room temperature for 3 minutes the sample was centrifuged at 12000 $\times g$ for 15 minutes at 4 °C. The upper aqueous phase was transferred into a new tube by angling the tube at 45° and pipetting the solution out. Afterwards the aqueous phase was mixed with 500 μ l of 100% isopropanol by inverting the tube. In order to precipitate the RNA the sample was incubated for 1 hour to overnight at -20 °C. The sample was centrifuged at 12000 $\times g$ for 15 minutes at 4 °C. The supernatant was removed and the RNA-pellet was washed with 1 ml of 75% ethanol for 5 minutes at room temperature. The sample was vortexed briefly and then centrifuged at 7500 $\times g$ for 5 minutes at 4 °C. The ethanol was removed and the pellet was allowed to dry on air. Afterwards the pellet was resuspended in nuclease-free water and incubated at 55 °C for 5 minutes. Concentration and quality was estimated by measuring the absorption at 230, 260 and 280 nm with a NanoDrop (Thermo Scientific). In addition, the RNA was monitored on an agarose gel to confirm that the isolated RNA was not degraded. The isolated RNA was stored at -80 °C. This protocol was adapted from the Ambion TRIzol® Reagent manual.

2.2.4 cDNA synthesis

The SuperScript® VILO™ cDNA Synthesis Kit (Life Technologies) was used for cDNA synthesis. Synthesis was carried out according to the manufacturer's manual. cDNA was used as template for cloning, the generation of single-stranded antisense in situ hybridization probes and double-stranded RNA fragments for RNAi. cDNA was stored at -20°C or -80°C.

2.2.5 Polymerase chain reaction (PCR)

All PCRs were performed on a C1000 or S1000 Thermal Cycler (Bio Rad, Hercules, US). REDTaq® ReadyMix™ (Sigma-Aldrich) was used to amplify fragments. cDNA or linearized plasmids were used as template. The components for a PCR reaction were pipetted on ice in a 0.2 ml PCR-tube. Table 3 shows a detailed list of components used for a PCR reaction.

After pipetting of all components the tube was transferred to a thermal cycler and the PCR reaction was carried out. Table 4 shows a typical PCR program. The elongation time was 1 min per 1 kb of desired product. The PCR product was checked on an agarose gel and if needed sequenced. The PCR products were kept at -20 °C.

Table 3: PCR components

Component	Amount per reaction
REDTaq® ReadyMix™	12.5 μ l
Primers (20 μ M)	0.5 μ l of each
cDNA template (50 ng/ μ l)	1 μ l
H ₂ O	Up to 25 μ l
Total	25 μ l

Table 4: Standard PCR program

Cycle number	Denature	Anneal	Elongate	Hold
1	94°C, 5 min			
2-36	94°C, 30 s	55-57°C, 30 s	72°C, 1 min	
37			72°C, 5 min	
38				4°C, forever

2.2.6 electrophoresis separation

To determine the presence and size of a particular PCR product, 5 µl of the reaction was run on a 1% agarose gel in 0.5x Tris-acetate-EDTA buffer at 135 V. To visualize the DNA 2 to 3 drops of 0.025 % ethidium bromide solution per 50 ml agarose were used. To identify the approximate size of a DNA fragment 2.5 µL of Smart Ladder MW 1700-10 (Eurogentec) was used as a molecular-weight size marker.

2.2.7 Cloning of PCR products

2.2.7.1 Transformation via electroporation

The Invitrogen™ TOPO™ TA Cloning™ Kit in combination with DH5α component *E. coli* cells were used and the instructions from the manuals were followed. Competent *E. coli* bacteria were stored at -80 °C and thawed on ice. After adding the ligation reaction, the bacteria were electro shocked at 1700 V. Immediately after the electroporation the cells were transferred into SOC medium and incubated at 37 °C for at least 1 h on a shaking incubator. Afterwards the bacteria were spread on LB-agar plates (LB medium plus 1.5% agar) with kanamycin, isopropyl β-D-1-thiogalactopyranoside (IPTG) and 5-Brom-4-chlor-3-indoxyl-β-D-galactopyranosid (X-Gal) and grown at 37 °C overnight. The pCR™II TOPO® TA vector contains a kanamycin resistance gene and the cloning site is located within the LacZ gene. Therefore bacteria with the pCRII vector were selected positively and it was possible to distinguish between colonies with an insertion in the pCRII vector (white) and with an empty vector (blue).

2.2.7.2 Extraction, purification, linearization and sequencing of plasmids

White colonies were picked and each was allowed to grow in 3 ml of LB medium with kanamycin at 37 °C overnight on a shaking incubator. The picked colonies were additional used as templates for colony PCRs with gene specific or M13 primers. For plasmid extraction the QUIAGEN Plasmid Miniprep Kit was used and all instructions from the manuals were followed. To examine the length of the cloned PCR products extracted plasmids were linearized with EcoRI and subsequent gel electrophoresis separation was performed. Finally the cloned PCR products were sequenced to confirm the cloning of the desired DNA fragments.

2.2.8 Template generation for RNAi and ISH

A two-step PCR strategy was used to amplify cDNA fragments with added T7 linkers as templates for either double-stranded RNA fragments for RNAi or single-stranded antisense mRNA probes for ISH. To each gene specific primer a linker sequence was added on the 5' end of each primer; for the forward (sense) primer "ggccgcgg" and for the reverse (antisense) primer "cccggggc" was added. The first PCR was carried out using standard PCR parameters (denaturation at 94 °C, annealing at 55 to 57 °C, elongation at 72 °C, 35 cycles), cDNA as template and gene specific primers with the described linkers for the gene of interest. The PCR products from the first PCR could be used to generate a template for both labeled antisense probes for ISH and double-stranded RNA fragments for RNAi, respectively. To generate a template for a labeled antisense probe a second PCR (using standard PCR parameters) was performed in which the PCR product from the first PCR was used as template together with the gene specific forward primer and the 3' T7 universal primer (agggatcctaatacactgactcactatagggccggggc). To generate a template for a double-stranded RNA fragment both the 3' T7 universal primer and the 5' T7 universal primer (gagaattctaatacactgactcactatagggccggg) were used together with the PCR product from the first PCR as template (using standard PCR parameters). The PCR products from the second PCR were used as templates for subsequent ISH probe and double-stranded RNA fragment synthesis, respectively.

2.2.9 Synthesis of dsRNA fragments for RNAi

To generate double-stranded (ds) RNA fragments the MEGAscript[®] KIT (Ambion) was used. First, a mastermix was prepared on ice containing 2 µl of each NTP (ATP, CTP, GTP and UTP), 2 µl T7 RNA Polymerase Enzyme Mix and 2 µl supplied 10x reaction buffer per reaction. The mastermix was briefly vortexed and quickly pipetted in individual reaction tubes (12 µl each). The gene-specific PCR templates (see section 2.2.8) or linearized plasmid were diluted with an equal amount of nuclease-free water and 8 µl of the diluted gene-specific PCR template was added. The reaction tubes were incubated overnight at 37 °C. The reaction was stopped by adding 115 µl water and 15 µl 10x ammonium acetate stop solution (5 M ammonium acetate, 100 mM EDTA). The dsRNA fragments were purified by adding 150 µl phenol/chloroform/isoamylalcohol (25:24:1). The reaction tube was vortexed for 1 minute and centrifuged at 5000 rpm for 5 minutes at 4 °C. The upper aqueous phase was transferred into a new tube by angling the tube at 45° and pipetting the solution out. Afterwards the aqueous phase was mixed with 150 µl of 100% isopropanol by inverting the tube. In order to precipitate the dsRNA the sample was incubated for 1 hour to overnight at -20 °C. The sample was centrifuged at 12000 rpm for 15 minutes at 4 °C. The supernatant was removed and the RNA-pellet was washed with 300 µl of 70% ethanol. The sample was again centrifuged at 12000 rpm for 5 minutes at 4 °C. The ethanol was removed via pipetting and the pellet was allowed to dry on air. Afterwards the pellet was resuspended in 50 µl nuclease-free water. Concentration and quality was estimated by measuring the absorption at 230, 260 and 280 nm with a NanoDrop (Thermo Scientific). In addition, the RNA was monitored on an agarose gel to confirm that the dsRNA was not degraded. The dsRNA was stored at -20 °C. This protocol was adapted from the MEGAscript[®] KIT (Ambion) manual.

2.2.10 Synthesis of labeled ISH probes

To generate single-stranded (ss) digoxigenin (DIG)-labeled antisense RNA in situ hybridization (ISH) probes reagents from Roche were used. First, a mastermix was prepared on ice containing 7.5 µl nuclease-free water, 2 µl DIG RNA labeling mix (Roche), 0.5 µl Protector RNase-Inhibitor (Roche), 2 µl T7 RNA Polymerase and 2 µl supplied transcription buffer (both from Roche) per reaction. The mastermix was briefly vortexed and quickly pipetted in individual reaction tubes (14 µl each). 6 µl gene-specific PCR template (see section 2.2.8) or linearized plasmid was added. The reaction tubes were incubated for 4 hours at 37 °C. The reaction was stopped by adding 30 µl water and 50 µl 2x ammonium acetate stop solution (10x ammonium acetate stop solution: 5 M ammonium acetate, 100 mM EDTA). 5 µl tRNA, 10 µl lithium chloride precipitation solution (7.5 M lithium chloride, 50 mM EDTA) and 300 µl ethanol (100%) were added and the probe was precipitated for 1 hour to overnight at -20 °C. Then the probe was centrifuged at 14000 rpm for 15 minutes at 4 °C. The supernatant was discarded and 300 µl ethanol (70%) was added. The reaction tube was briefly vortexed and again centrifuged at 14000 rpm for 5 minutes at 4 °C. All supernatant was discarded via a pipette and the pellet was allowed to air dry. Finally the pellet was resuspended by pipetting in 100 µl probe resuspension buffer (formamide 50 %, 2x SSC). The resuspended probes were stored at -20°C. This protocol was adapted from the MEGAscript® KIT (Ambion) manual.

2.2.11 Generation of parental RNA interference knockdown embryos

To generate parental RNA interference (pRNAi) knockdown embryos for a particular gene of interest 5 µl dsRNA at concentrations of 1000 ng/µl was injected into adult virgin females of *Oncopeltus*. Injections were performed using a 10 µl syringe (Hamilton). The method of RNAi knockdown generation exploits an ancient defense mechanism against double-stranded (ds) RNA viruses that is thought to be present in most multicellular organisms (Jinek and Doudna, 2009). dsRNAs that often result from viral infection and transcription are recognized and cleaved by Dicer, an RNase III family protein. Thereby small dsRNAs (21-25 nucleotides) are generated, which are labeled via mono-phosphate groups on their 5'-ends and dinucleotide overhangs on their three 3'-ends. These small dsRNAs are bound by argonoute proteins. This association forms the core complex of the RNA induced silencing complex (RISC). The argonoute proteins are responsible for the cleavage and binding of the target single-stranded RNA (ssRNA). This mechanism can be experimentally used to knock down gene expression by injection of long dsRNA molecules (about 200 bp to 1.5 kb) corresponding to an exonic region of the respective target gene. This leads to a knockdown of the target gene via mRNA degradation. This method is very successful and easy to apply in *Oncopeltus*. It is possible to perform (pRNAi) knockdowns via injection of dsRNA into adult females. Embryos with a loss of function phenotype can be obtained for up to four weeks (Liu and Kaufman 2004), except immunity-relevant genes are targeted, e.g. *Toll*, which leads to drastically increased mortality of injected female after about one week and therefore decreases knockdown embryo yield.

2.2.12 In situ hybridization protocol

This in situ hybridization (ISH) protocol was adapted from the previously published ISH protocol for *O. fasciatus* by Liu and Kaufman, 2005. The ISH protocol was always performed within a timeframe of 3 days.

2.2.12.1 Embryo preparation before hybridization

The embryos were stepwise transferred from 100% methanol to 1x PBST and then washed with 1x PBST (2x 5 minutes, 1x 1 hour). Subsequently the embryos were gradually transferred into hybridization buffer and washed twice in hybridization buffer for 5 minutes. In order to inactivate the endogenous alkaline phosphatase the embryos were incubated at 70 °C for 30 minutes. Subsequently the embryos were prehybridized by incubation at 60 °C for at least 30 minutes.

2.2.12.2 Hybridization reaction

5 µl probe was added to 495 µl hybridization buffer. Hybridization was performed at 60 °C overnight (end of day 1). The specificity of the hybridization of nucleic acids depends largely on an appropriate concentration of formamide, salts and on a suitable temperature. Salt (SSC, SDS) promoted hybridization because the positively charged cations neutralized the negative charge of the phosphate backbone of nucleic acids. Additionally, formamide is a hydrogen bond breaking substance that prevented unspecific hybridization. A high temperature also hindered unspecific hybridization. Moreover, ssDNA also inhibited unspecific hybridization because it blocks and saturates nucleic acids via unspecific bindings which then are replaced by specific bindings from the antisense probe to sense mRNA. tRNA is added to protect the RNA probe against nucleases by competitive inhibition. Since the concentration of tRNA was much higher than the probes concentration, tRNA was more likely a substrate for nucleases than the probe was.

2.2.12.3 Removal of excessive probe

Excessive probe was removed by six washes in hybridization buffer at 60 °C (2x rinsed, 4x 20 minutes) and two subsequent washings at room temperature (2x 5 minutes) first in 5x SSC/ 50% formamide/ 0.1% Tween-20 and second in 2x SSC/ 50% formamide/ 0.1% Tween-20. Afterwards the embryos were gradually transferred into 1x PBST and then washed in 1x PBST (2x rinsed, 2x 20 minutes). Afterwards the embryos were once rinsed and subsequently blocked for 2 hours at room temperature in blocking solution.

2.2.12.4 Probe detection

The anti-digoxigenin::alkaline phosphatase (α -DIG::AP) antibody (Roche, Fab fragments from sheep, applied dilution 1:2000) and the nucleic acid stain SYTOX-green (Nuclear probes) was added in fresh

blocking solution. The embryos were incubated overnight at 4 °C (end of day 2). The excessive antibody was removed by several washes in 1x PBST at room temperature (4x rinsed, 4x 20 minutes). The embryos were stepwise transferred into alkaline phosphatase (AP) buffer. This buffer contains ions and has an alkaline pH, which enables the enzyme to catalyze efficiently. After several washings in AP buffer (2x rinsed, 1x 30 minutes) nitro blue tetrazolium chloride/5-bromo-4-chloro-3-indolylphosphate (NBT/BCIP; Sigma-Aldrich) solution was added in fresh buffer to initiate the color reaction. Alkaline phosphatase dephosphorylates BCIP which becomes then oxidized by NBT and adds to a blue indigo colorant while NBT is reduced to a blue diformazan. The reaction was stopped by several washes in 1x PBST.

2.2.13 Fuchsin staining

Fixed embryos (see section 2.2.2) were transferred into glass vials and washed in 70% ethanol (4x 20 minutes). The ethanol was removed, 2 N HCl were added and the embryos were incubated at 60 °C for 10 minutes. Afterwards one washing with distilled H₂O (5 minutes) and two with 70% ethanol (2x 5 minutes) were performed. Subsequently the embryos were incubated in alcoholic fuchsin staining solution for 30 minutes. Then excessive color was removed by washing in 95% ethanol (3x 20 minutes). Afterwards the embryos were dehydrated by washing in 100% ethanol (2x 3 minutes). The ethanol was removed and solution C was added. As soon as the embryos sank to the bottom of the tubes, solution C was substituted by solution D. The BBBA alcohol mixture is responsible for optical clearing of the yolk. The stained embryos were stored at 4 °C, protected from light. This protocol was based on Lena Sachs fuchsin staining protocol (Sachs, PhD thesis, 2014).

2.2.14 mRNA synthesis protocol

The mMessage mMachine[®] SP6/T7 Kit (Ambion) was used for capped mRNA synthesis. Synthesis was carried out according to the manufacturer's manual. Linearized plasmids were used as templates. The plasmid pCS2-zfChd (vector: pCS2+; insert: *Danio rerio chordin* cDNA; bacterial resistance: ampicillin; linearized with: NotI; sense transcription with: SP6) was kindly provided by the Matthias Hammerschmidt lab. The plasmid pUC57-Eos-NLS-PolyA (vector: pUC57; insert: *Eos-NLS* cDNA; bacterial resistance: ampicillin; linearized with: BamHI; sense transcription with: SP6 or T7) was kindly provided by Matthias Pechmann. Capped mRNA was microinjected into *O. fasciatus* blastoderm stage embryos at concentrations between 1500 to 3000 ng/μl. Capped mRNA was stored at -20°C and thawed not more than 3 times before being discarded.

2.2.15 Dechoriation of *Of* embryos for microinjections

In order to perform embryonic microinjections *Oncopeltus* embryos were partially dechorionated to enable needle penetration. Complete dechoriation established for other insect embryos like *Drosophila* or *Tribolium* was not possible in *Oncopeltus* since the dechoriation agent enters *Oncopeltus* embryos through the micropyles and completely dissolved the entire embryo before dechoriation was achieved.

Partial dechoriation was achieved with two different methods. For a strong but less uniform partial dechoriation two small stripes of cellulose filter paper (Whatman) were saturated with DanKlorix (Colgate-Palmolive). The embryos were lined up on the first stripe in a way in which the most anterior part including the micropyles was not touching the stripe. The second stripe was placed on top in an analogous manner. After 5 minutes of exposure to DanKlorix embryos were rinsed with water 3 times. For a more uniform but less strong partial dechoriation embryos were transferred into 50% DanKlorix for 5 minutes and subsequently rinsed with water 3 times to remove DanKlorix.

2.2.16 Needle preparation for embryonic microinjections

Our lab routinely microinjects embryos from various arthropods with borosilicate glass needles. Unfortunately the chorion of *Oncopeltus* embryos is too resistive to be penetrated with such needles even after partial dechoriation. Instead I used quartz glass needles (with filament; outer diameter 1 mm; inner diameter 0,5 mm; length 100 mm; Sutter Instrument item #: QF100-50-10). Those needles were pulled on a P-2000 micropipette puller (Sutter Instrument) using the following quartz glass specific program:

Heat	Filament	Velocity	Delay	Pull
825	5	50	145	175

Unlike borosilicate glass needles which can be opened by polishing on a grinder quartz glass needles had to be cut open with a razor blade since they were too rigid to be polished.

2.2.17 Embryonic microinjections

1% agarose gel was poured into a Petri dish and long slits were cut into the cooled down gel with a razor blade. Partially dechoriated embryos (see 2.2.15) were pushed into these slits with a brush and covered with halocarbon oil (Votalef H10S, Arkema). Protein or mRNA was backloaded into quartz glass needles which were cut open with a razor blade. Embryos were injected under a microscope using a microinjector (PLI-100A Pico-Injector, Warner Instruments). After injection embryos were left within the agarose slits and placed into their regular incubator.

Several parameters within this injection protocol could not be standardized and therefore the injection amount was necessarily variable and difficult to quantify, ranging from about 0.05 % to 5 % of overall egg volume. Varying parameters included depth of injection and bevel angle of the needles.

2.2.18 RNA sequencing

RNA was isolated and purified as described in 2.2.3. RNA quantity and quality was checked using a Thermo Scientific Nanodrop 2000C Spectrophotometer and 2 µg was sent for sequencing by the Cologne Centre for Genomics (CCG) on an Illumina HiSeq 2000 sequencer after sample preparation using a TruSeq RNA Library Preparation Kit (Illumina). Samples were sequenced on one lane per

species. Adaptor trimming and initial quality control was performed by the provider according to their proprietary standards, and after exclusion of complete reads, no orphan reads were kept. This cleaned data was then made available to us for download from an external server. Paired end read quality after sequencing was assessed using the FastQC program (Andrews, 2010) and no residual adaptor was observed.

2.2.19 Transcript Quantification and Differential Expression Analyses

Transcript Quantification was made using the Trinity toolkit together with the alignment-based quantification method RSEM (Grabherr et al., 2011; Li and Dewey, 2011). Trimmomatic (Bolger et al., 2014) was assayed (Illuminaclip Leading:3 Trailing:3 Slidingwindow:4:15 Minlen:36) but not utilized. DeconSeq standalone version 0.4.3 (Schmieder and Edwards, 2011) was run on full assemblies with settings -i 95 -c 95, using the bact, fungi, hsref, and prot databases. Differential expression analyses were performed by mapping reads from individual samples (RNAi knockdowns and wild-type) to the Official Gene Set (OGS v1.2) of *Oncopeltus fasciatus* (Panfilio et al., 2019) using RSEM with Bowtie (Langmead et al., 2009) as packaged in the Trinity module (align_and_estimate_abundance.pl script,—est_method RSEM—aln_method bowtie) to compare the individual samples with each other. The abundance_estimates_to_matrix.pl script was then run (cross sample normalization: Trimmed Mean of M-values). edgeR (Robinson et al., 2010) was then run using the run_DE_analysis.pl script and the most differentially expressed transcripts were extracted and clustered using the analyze_diff_expr.pl script, p-value cut off for FDR of 0.05 and fold change of 2, with—gene_dist euclidean and—gene_clust.complete.

3. Results

3.1 Knockdown of *Of-snail*

Most of the conserved components of insect DV axis patterning had been analyzed in *Oncopeltus* in previous work (Sachs, PhD thesis, 2014; Chen, PhD thesis, 2015; Sachs et al., 2015). However, a knockdown of *Of-snail* was never described. I performed a pRNAi-mediated *Of-snail* knockdown and analyzed the phenotype by fuchsin staining (Fig. 9 E) and ISH experiments with DV and AP marker genes (Fig. 9 A-D). Embryos lacking *Sna* exhibited a strong lethal phenotype in which a head was formed at the posterior end but thoracic and abdominal segments seemed to be lacking, indicating impaired germ band formation and defective katanaprepis (Fig. 9 E). The expression of *OFAS016851* in *Of-snail* knockdown embryos is similar to its wild-type expression pattern (Fig. 9 C, compare to Fig. 26 A). However, the expression of the mesodermal markers *sog* and *twi*, and of the mesectodermal marker *sim* was derepressed in *Of-sna* knockdown embryos, that is, their expression was uniform around the embryonic circumference (Fig. 9 A, B, C). While the derepression of *sog* and *twist* is seen in several knockdown conditions which lack BMP signaling (e.g. in *dpp* and *tld* knockdown embryos) (Sachs et al., 2015), the expression of *sim* within the derepressed mesoderm is a distinctive characteristic of *snail* knockdown embryos.

Figure 9: pRNAi-mediated knockdown of *Of-snail*

(A-E) *Of* embryos lacking Snail, anterior to the left; (A-D) embryos were fixed 24-30 hpf (hours post fertilization); (A) expression of *sog*; (B) expression of *twist*; (C) expression of *sim*; (D) expression of *OFAS016851*; (A'-D') same embryo as depicted in pictures labeled with corresponding capital letters, nuclei stained with SYTOX Green; (E) fuchsin staining. Embryo was fixed 144 hpf. Position of the eyes is marked with black arrowheads.

3.2 Establishment of embryonic injections

In order to perform the desired DV network manipulations in *Of* blastoderm embryos a practical injection method had to be developed (see 2.2.15 – 2.2.17). To test the injection method early blastoderm stage embryos (18 - 24 hpf) were injected with dd H₂O as negative control (Fig. 10). The injected embryos developed and hatched wild-type-like in 91,76% of observed cases (n=182). 8,24% of injected embryos exhibited unspecific developmental arrests before or during germ band formation, presumptively caused by the injection process itself. Hughes and Kaufman who first published a similar though less sophisticated injection protocol for *Of* reported a 50% rate of developmental arrests in their negative control experiments (Hughes and Kaufman, 2000).

The location of needle penetration for these initial and each of the following injection experiments was between 25 and 50 % of egg length (posterior is 0%) from lateral position to ensure injections into presumptive mesodermal or ectodermal regions. Anterior and posterior of *Oncopeltus* embryos were easy to distinguish by the anterior positioned micropyles. Unfortunately the embryos looked uniform along their DV axis during blastoderm stage. Therefore it was not possible to aim injections specifically for distinct regions along the DV axis like for example the mesoderm. However, in nuclear staining of embryos fixed 6h after injection an injection-wound was frequently visible and therefore allowed to locate the site of injection.

Figure 10: *Of* embryos after injection of water

(A - C) Water-injected *Of* wild-type embryos shortly before hatching, anterior to the left. Injections were performed at early blastoderm stage between 18 - 24 hpf; (A) lateral view; (B) ventrolateral view; (C) dorsal view.

3.3 Microinjection of human BMP4 protein into *Of* embryos

The first successful embryonic microinjections which induced DV aberrations during axis formation in *Oncopeltus* were performed using commercially available human BMP4 protein (Thermo Fisher Scientific; PHC9534) (Fig. 11 - 13). It has been shown before that vertebrate BMP4 is able to activate the BMP signaling pathway in arthropod species and vice versa (Padgett et al., 1993; Pechmann, 2020; Sampath et al., 1993). Early blastoderm stage embryos (18 - 24 hpf) were microinjected with

different BMP4 concentrations and either fixed at late blastoderm stage (24 - 30 hpf) for ISH experiments (Fig. 13) or photographed after 6 more days of development, when the negative controls were about to hatch (Fig. 11 - 12). As negative control to exclude unspecific protein injection effects like an immune response I injected BSA at similar concentrations which did not seem to disturb embryogenesis.

Embryos injected with high concentrations (100 µg/ml) of BMP4 show strong phenotypes in which the embryo developed into a large agglutination of yolk connected with a small cuticulized part of embryonic tissue (94,77 % n=153) (Fig. 11). Injections with moderate concentrations of BMP4 (10 - 20 µg/ml) lead to milder but nevertheless still strong phenotypes in which the embryos developed heads with visible eyes and mouthparts, but thoracic and abdominal segments failed to develop correctly (Fig. 12 A - B). Defective katarrepsis occurred as well (Fig. 12 A). In some cases the embryos injected with moderate concentrations of BMP4 hatched wild-type-like or showed late developmental arrests after katarrepsis (Fig. 12 C - D).

In situ hybridization for *sog* transcripts revealed that around the injection site of moderate BMP4 concentrations the endogenous expression of *sog* is disturbed (Fig. 13). Cells in proximity to the injection site show either weaker or no staining, indicating reduced or absent *sog* expression (Fig. 13). In situ hybridizations for *sog* transcripts performed on embryos which were injected with high concentrations of BMP4 do either not show visible staining or chaotic and disorganized patches of *sog* expression (data not shown).

Figure 11: *Of* embryos after injection with high concentration of human BMP4

(A - D) Embryos were injected with high concentrations of human BMP4 18 - 24 hpf and photographed 96 h later, anterior to the left.

Figure 12: *Of* embryos after injection with moderate concentrations of human BMP4

(A - D) Embryos were injected with moderate concentrations of human BMP4 18 - 24 hpf and photographed 96 h later, anterior to the left.

Figure 13: *sog* expression after injection of BMP4

(A - F) *sog* expression in late blastoderm stage embryos fixed 24 - 30 hpf after injection of human BMP4 at 18 - 24 hpf, anterior to the left; (A' - F') same embryo as depicted in pictures labeled with corresponding capital letters, nuclei stained with SYTOX Green; (A - F') A - C' and D - F' show the same embryo, respectively; (A, A', D and D') ventral view; (B, B', E and E') lateral view; (C, C', F and F') magnification of corresponding lateral views (C' and F') location of injection marked with white asterisk.

3.4 Microinjection of *eosFP-nls* mRNA into *Of* embryos

After successful embryonic microinjections of proteins, I tried mRNA injections. To test whether the injected mRNA remained rather local or tended to distribute throughout embryos I injected *eosFP-nls* mRNA into *Of* blastoderm embryos 18 - 24 hpf. *eosFP-nls* mRNA codes for a fluorescent marker protein and contains a nuclear localization sequence. 2 - 6 h after injection the *eosFP-nls* mRNA was translated into detectable protein (Fig. 14 B - D). The localization of EosFP-positiv nuclei depends on the depth of injection. Deep injections into the yolk generate EosFP-positiv yolk nuclei (Fig. 14 B), whereas injections close to the egg surface induce spatially restricted EosFP-positiv blastodermal nuclei (Fig. 14 C - D).

Figure 14: *Of* embryos injected with *eosFP-nls* mRNA

(A) Wild-type *Of* blastoderm stage embryo stained with SYTOX Green; **(B - D)** embryos injected with *eosFP-nls* mRNA 18 - 24 hpf and photographed while alive 2 - 6 h after injection; **(B)** localization of EosFP in yolk nuclei; **(C - D)** EosFP-positive blastodermic nuclei are spatially restricted around the injection site.

3.5 Microinjection of *Danio rerio chordin* mRNA into *Of* wild-type embryos and embryos lacking Toll

After successful manipulations of the DV network during *Of* embryogenesis via microinjections of BMP components which lead to disturbance of the mesoderm, I planned DV manipulations via injections of BMP antagonists. A previous published *eLife* article shows that in *Oncopeltus* the BMP antagonist Sog polarizes the BMP network and that mesodermal fates are not strictly reliant on Toll (Sachs et al., 2015). Following the logic of the article an injection of *sog* into the dorsal side of wild-type *Of* embryos should be sufficient to induce ventral fates. In addition an injection of *sog* into dorsalized *Of* embryos lacking Toll should also induce ventral fates. I show here that these inductions of ventral fates via ectopic polarization of the BMP gradient by microinjection of BMP antagonists are indeed possible, both in wild-type and in a dorsalized embryonic phenotype (Fig. 15 - 22).

Since *sog* itself is expressed in the ventral ectoderm and presumptive mesoderm of *Oncopeltus* embryos it is often used in ISH experiments as ventral marker. mRNA microinjections of *Of-sog* would not allow to distinguish microinjected *sog* from endogenous *sog* produced by the embryo itself in ISH experiments. To overcome this problem I injected *Danio rerio chordin*, the vertebrate homolog of *sog* into *Of* embryos. Vertebrate BMP antagonists like Chordin and Noggin have been shown to repress BMP activity in insects and vice versa (Holley et al., 1996; Yu et al., 2000; Schmidt et al., 1995).

Dr-chordin was microinjected at concentrations between 1500 - 3000 ng/ml into early blastoderm stage embryos (18 - 24 hpf), which were either fixed at late blastoderm stage (24 - 30 hpf) for ISH experiments (Fig. 18 - 22) or photographed after 6 more days of development, when the negative controls were about to hatch (Fig. 15 -17).

Microinjections with *chordin* caused a range of different injection phenotypes. The strongest injection phenotypes were lethal and showed defective gross morphology (Fig. 15), sometimes including defective katabolism (Fig. 15 A - B). Moderate injection phenotypes were lethal as well and showed defective segmentation boundaries leading to fused tergites (Fig. 16 C, E and F) and fused legs (Fig. 16 B and D). The weakest injection phenotypes were viable and showed irregular shortened and thickened appendages (Fig. 17 A - C) or dented tergites (Fig. 17 D). This range of phenotypic effects and severity was most likely caused by the location of the injection site (dorsal, lateral or ventral) and the necessarily variable injection amount (see 2.2.17).

Figure 15: Cuticle preparations of strong *chordin* injection phenotypes

(A - D) Wild-type embryos were injected with *Dr chordin* 18 - 24 hpf and mounted in Hoyer's medium 96 h later, anterior to the left. Position of the eyes is marked with black arrowheads.

Figure 16: Moderate *chordin* injection phenotypes

(A - F) Wild-type embryos were injected with *Dr chordin* 18 - 24 hpf and photographed 96 h later, anterior to the left. Irregular formed structures are marked with black dotted boxes. A - D and E - F show the same embryo, respectively; (D) magnification of B.

Figure 17: Weak *chordin* injection phenotypes

(A - D) Wild-type embryos were injected with *Dr chordin* 18 - 24 hpf and photographed 96 h later, anterior to the left. Irregular formed structures are marked with black dotted boxes.

ISH experiments on microinjected *Of* wild-type embryos revealed that the presence of ectopic *chordin* is sufficient to induced the expression of mesodermal marker genes *twist* (Fig. 18) and *sog* localized around the site of injection (Fig. 19 and 20). Lateral microinjections induced an expansion of the ventral expression domain of *sog* to the lateral side (Fig. 19 c and c'). Dorsal microinjections induced ectopic expression of *twi* (Fig. 18) and *sog* (Fig. 19 D - F' and 20) on the dorsal side.

The area of ectopic *twi*-positive and *sog*-positive cells on the dorsal side was frequently shaped either like a small solid patch (Fig. 19 D - F') or like a ring with *twi*-negative and *sog*-negative cells in its center (Fig. 18 and 20). Some embryos showed a fading weak sporadic expression of mesodermal markers within such rings (Fig. 20). It could be possible that these embryos were fixed during a transition process from a small solid spot to a wider ring of ectopic mesodermal marker gene expression.

Nuclear density within the region of ectopic *twi* (Fig. 18 C, C', F, F', I and I') and *sog* (Fig. 20 C, C', E, E', F and F') expression on the dorsal side was lower than in the surrounding *twi*-negative and *sog*-negative dorsal region, respectively. Nuclear density can be used to distinguish dorsal and ventral regions of *Oncopeltus* embryos. At the dorsal side nuclear density is higher than at the ventral side (Sachs et al., 2015). Thus the ectopic *twi*-positive and *sog*-positive regions on the dorsal side resembled a more ventral-like nuclear density.

Oncopeltus embryos lacking Toll are dorsalized and do not express *sog*, *twi* and *sim* along their DV axis (Sachs et al., 2015). However, after injection of *chordin* into *Of-Toll* pRNAi knockdown embryos ISH experiments revealed that around the site of injection expression of *sog* and *sim* is induced (Fig. 21 and 22). *sog* was expressed either in a large solid patch or a ring with a patch in its center (Fig. 21). *sim* was expressed in wide rings with single *sim*-positive cells within those rings (Fig. 22). The injection-induced expression patterns in embryos lacking Toll were similar to those of dorsally injected wild-type embryos. However, the observed patches and rings were wider in embryos lacking Toll than in wild-type embryos. Similar to observations made in dorsally injected wild-type embryos, nuclear density within the patches and rings of *sog* and *sim* expression is lower than in the unstained regions of *chordin*-injected dorsalized *Toll*-knockdown embryos (Fig. 21 and 22).

Figure 18: *twi* expression after injection of *Danio rerio chordin* mRNA into *Of* wild-type embryos

(A - I) *twi* expression in late blastoderm stage embryos fixed 24 - 30 hpf after injection of *Dr chordin* at 18 - 24 hpf, anterior to the left; (A' - I') same embryo as depicted in pictures labeled with corresponding capital letters, nuclei stained with SYTOX Green; (A - I') A - C', D - F' and G - I' show the same embryo, respectively; (A, A', D, D', G and G') lateral view; (B, B', E, E', H and H') dorsal view; (C, C', F, F', I and I') magnification of corresponding dorsal views, *twi* staining enframed by white dotted line; (C' F' and I') location of injection marked with white asterisk.

Figure 19: *sog* expression after injection of *Danio rerio chordin* mRNA into *Of* wild-type embryos

3.6 Differential expression analysis (RNAseq) of dorsalized and ventralized *Oncopeltus* embryos

Changes in gene expression, induced via genetic manipulations, can be investigated by differential expression analysis (Wang et al., 2009; Stappert et al., 2016). To identify differentially expressed transcripts, the transcriptomes of manipulated specimens are compared to wild-type transcriptomes. I generated transcriptomes of ventralized and dorsalized phenotypes by knocking down crucial components of *Toll* and *BMP* signaling by parental RNA interference (pRNAi) in the large milkweed bug *Oncopeltus fasciatus* in order to find new marker genes of the embryonic fate map and potentially identify novel components of DV signaling that were not found before by using the candidate gene approach. For each knockdown condition I generated a triplicate of biological replicates to make the subsequent analysis more robust. The different knockdown conditions were: (1) a pRNAi *Toll* knockdown which led to a complete dorsalization and a loss of the most anterior fate of *Oncopeltus* embryos, (2) a pRNAi *sog* knockdown which also led to a complete dorsalization but without any anterior-posterior patterning effect, (3) a pRNAi *tld* knockdown which led to a complete ventralization similar to *dpp* knockdowns (*dpp* knockdown embryos were considered as a transcriptome candidate but collection of embryos was discontinued because of a sterility effect in *dpp* pRNAi injected females), (4) a pRNAi *gbb* knockdown which lead to a weaker pronounced

dorsalization/lateralization, (5) a pRNAi *gfp* knockdown as negative control to account for unspecific pRNAi effects, (6) and a wild-type control from untreated mothers. All embryos were collected between 24 and 30 hpf at 25 °C which corresponded to a time frame from differentiated blastoderm stage, when important DV genes like *sog* were expressed robustly in the presumptive mesoderm, to late blastoderm stage, when the embryo started to condense and invaginate at the posterior. The embryo collection was tightly staged for each knockdown condition and the total RNA was isolated using standard TRIzol protocols. The isolated total RNA was brought to the Cologne Center for Genomics (CCG) which synthesized cDNA from the total RNA and sequenced it on a single lane on an Illumina HiSeq4000 sequencer. Paired-end sequencing technique was used with read lengths of 75 bp per end and a total insert size of 180 bp. Subsequent RNA-seq analysis was carried out in collaboration with Nathan J. Kenny (PostDoc at Oxford Brookes University). A subsequent in situ hybridization screen was carried out in order to identify genes with an asymmetric localization along the DV axis among the candidates gained by differentially expression analysis. Differentially expressed genes for the ISH screen were chosen by several criteria; genes with potentially interesting gene products (i.e. transcription factors or components of signaling pathways); strongly differential expressed genes based on different thresholds of fold changes (FC); genes that overlapped in several knockdown conditions in Venn diagrams (i.e. down-regulated in dorsalized but up-regulated in ventralized embryos) (Fig. 23). False discovery rate (FDR) cut-off was at least ≤ 0.05 for each criteria. Genes achieved from ISH screening with spatial restricted expression along the dorsoventral axis (Fig. 24 – 26 and 28) were additionally tested for a knockdown phenotype via pRNAi (Fig. 27).

Figure 23: Venn diagram for mesodermal candidate genes

Venn diagram of differentially expressed genes from various pRNAi knockdown embryos compared to wild-type embryos; knockdown conditions were: *Tl* knockdown (dorsalized), *sog* knockdown (dorsalized) and *tld* knockdown (ventralized); blue circle displays genes that are upregulated upon *Tl* knockdown compared to wild-type blastoderm stage embryos; red circle displays genes that are upregulated upon *sog* knockdown compared to wild-type blastoderm stage embryos; green circle displays genes that are upregulated upon *tld* knockdown compared to wild-type blastoderm stage embryos; fold change cut-off was ≥ 2 ; false discovery rate cut-off was ≤ 0.05 .

Knockdown embryos that lack *Tl* or *sog* underexpress genes that are normally expressed within the mesoderm, while embryos that lack *tld* overexpress mesodermal localized gene transcripts. Vice versa ectodermal localized gene transcripts should be upregulated in dorsalized and downregulated in ventralized embryos. A useful strategy to narrow down potential candidate genes, besides increasing the FC and decreasing the FDR, is to create Venn diagrams and focus on genes that overlap in more than one knockdown condition. A similar approach using microarray assays was successfully used in *Drosophila* to identify new Dorsal target genes (Stathopoulos et al., 2002). By generating Venn diagrams with this approach and subsequent ISH screening I identified four novel genes, *OFAS000625*, *OFAS009424*, *OFAS016851* and *OFAS018039*, which exhibit localized expression patterns in *Oncopeltus* blastoderm stage embryos (Fig. 24 – 26 and 28).

Figure 23 shows a Venn diagram that was used to identify mesodermal candidate genes in which genes that were downregulated in *Toll* and *sog*, but upregulated in *tld* knockdowns compared to wild-type embryos were overlapped against each other. Among the differential expressed genes was the known DV patterning key component *sog*, which was downregulated in *Toll* and *sog* knockdown, but upregulated in *tld* knockdown, which is consistent with in situ hybridization experiments in these knockdown conditions and wild-type embryos (Sachs et al., 2015). However, *Toll* was not downregulated in *sog*, but only in *Toll* knockdown which was expected for the ubiquitous expressed receptor. The anteriorly expressed gene *tailless* was downregulated in *Toll*, but not in *sog* knockdown embryos. This is consistent with the observation that in *Toll* knockdown embryos, besides dorsalization, the most anterior fates are lost, a region of the embryo which is thought to give rise for the serosa and parts of the head fate map (Sachs et al., 2015). Also downregulated in *Toll* knockdown were *OFAS018039* and *OFAS016851*, and subsequent in situ screening identified both as anterior expressed genes, and their expression profiles, gene products and phenotypes are described later in section 3.8 and 3.9 (Fig. 26 - 28). Like *tailless*, *OFAS018039* was only downregulated in *Toll*, but not downregulated in *sog* knockdown, which is consistent with the observed loss of the most anterior fates in *Toll* knockdown embryos. However, *OFAS016851* was downregulated in both *Toll* and *sog* knockdown embryos, which was unexpected since the anterior fates are usually not affected by a lack of Sog. Downregulated in both *Toll* and *sog* knockdown were *vnd* and *brk* which are known Type 2 Dorsal target genes in *Drosophila*. However, in *Oncopeltus* *vnd* is expressed in an anteroventral domain (Chen, PhD Thesis, 2015) and a localized expression of *brk* was not detectable via ISH (data not shown). However, a downregulation of both *vnd* and *brk* in dorsalized *Toll* and *sog* knockdown embryos would be consistent with the current understanding of *Oncopeltus* DV axis patterning. *noggin*, a BMP signaling antagonist which is not present in *Drosophila*, but in vertebrates was upregulated in *tld* knockdown embryos. In *Xenopus* *noggin* is expressed in the Spemann organizer region, promotes mesodermal cell fates and induces neural formation in the overlying ectoderm (Holley et al., 1996). A localized expression pattern of *noggin* was not detectable via ISH (data not shown), however an upregulation of *noggin* in mesodermalized *Oncopeltus* embryos would be consistent with the expression patterns of *noggin* in vertebrates. pRNAi knockdowns of *noggin* and *brinker* were performed, but did not lead to a notable phenotype (data not shown). Downregulated in *sog* knockdown was *OFAS000625*, a gene which has an expression pattern similar to *sog* in *Oncopeltus* blastoderm stage embryos. *OFAS000625* gene product and expression pattern profile is described in more detail later in section 3.7 (Fig. 24).

Another gene whose transcripts turned out to be localized in blastoderm stage embryos was *OFAS009424*. *OFAS009424* expression seems to be associated with nuclear density and was strongly localized on the lateral sides, but expression on the dorsal and ventral side, where the nuclear density is lower, was weaker (Fig. 25). The condensation of the lateral sides of blastoderm stage

embryos which forms a region of high nuclear density was disturbed in dorsalized embryos and therefore a downregulation of *OFAS009424* in *Toll* and *sog* knockdown embryos is consistent with the observed interrelation of transcript expression and nuclear density.

Delta (Dl) was downregulated in *sog* but upregulated in *tld* knockdown, which is comparable to RNAseq and ISH data from *Tribolium*, where *Delta* is expressed in the presumptive mesoderm and repressed in the ectoderm (Stappert et al., 2016). However, in *Drosophila* *Delta* is repressed in the presumptive mesoderm and shows graded expression in the neurogenic ectoderm (Vassin et al., 1987). A localized expression of *Delta* was not detectable via ISH in *Oncopeltus* blastoderm stage embryos (data not shown). *Patched-related (Ptr)* was downregulated in *Toll* but upregulated in *tld* knockdown embryos, which seems to be strikingly different from *Drosophila*, where *Ptr* is expressed in the ventral and dorsal ectoderm (Fisher et al., 2012). A localized expression of *Ptr* was not detectable via ISH in *Oncopeltus* blastoderm stage embryos (data not shown).

A complete list of all differential expressed genes within this Venn diagram is enclosed in the appendix.

3.7 Analysis of *OFAS000625*

OFAS000625 was downregulated in *sog* knockdown embryos compared to wild-type control embryos of *Oncopeltus*. Therefore it was selected as an ISH screen candidate. The spatial and temporal expression patterns of *OFAS000625* in *Oncopeltus* late blastoderm stage wild-type embryos are shown in Figure 24.

At 24 hpf *OFAS000625* was expressed similar to transcripts of *sog* in a broad ventral stripe encompassing approximately 60 % of the embryo from posterior while omitting the anterior 40 % of the embryo. In between 24 to 30 hpf a ring-like second domain of transcript expression emerged which encompassed 70 to 80 % of egg length from anterior and spanned around the whole DV axis of the embryo. Expression patterns similar to *OFAS000625* late blastodermic expression have never been reported for *Oncopeltus* embryos in the literature before.

Because of *OFAS000625* asymmetric expression pattern along the DV axis it was further analyzed via pRNAi-mediated knockdown. However, the knockdown did not result in a developmental or otherwise notable phenotype.

Bioinformatic analysis with various tools like BLAST and Conserved Domain Search showed that *OFAS000625* exhibits homologies to genes of several insect orders (Lepidoptera, Coleoptera and Hymenoptera, Hemiptera, and Blattodea). However, bidirectional BLAST could not find a clear ortholog for *OFAS000625*. The only conserved domain that was detected in *OFAS000625* is the Baculo_F super family domain which is found in a variety of baculoviruses and some presumed transposons (Pearson et al., 2000).

Figure 24: Spatial and temporal expression patterns of *OFAS000625*

(A - L) Expression patterns of *OFAS000625* revealed by ISH in *Of* late blastoderm stage wild type embryos, 24-30 hpf, anterior to the left; (A' - L') same embryo as depicted in pictures labeled with corresponding capital letters, nuclei stained with SYTOX Green; (A - D') ventral view, age is increasing; (E - H') lateral view, age is increasing; (I - L') dorsal view, age is increasing.

3.8 Analysis of *OFAS009424*

Compared to wild-type control embryos *OFAS009424* transcript expression was downregulated in *sog* and *Toll* knockdown embryos. Therefore *OFAS009424* was selected for ISH screening. The spatial expression patterns of *OFAS009424* in late blastoderm stage embryos are shown in Figure 25.

In late blastoderm stage embryos *OFAS009424* was expressed strongly on the lateral sides, moderately on the dorsal side and only weakly on the ventral side in a “salt and pepper”-like expression pattern (Fig. 25). This expression pattern seemed to be correlated with nuclear density which is highest on the lateral sides and lowest on the ventral side of *Oncopeltus* embryos. *OFAS009424* was not expressed in the anterior region of blastoderm embryos, omitting about 40 % of the anterior pole. Expression patterns similar to *OFAS009424* late blastodermic expression have never been reported for *OF* embryos in the literature before.

Because of its asymmetric expression pattern along the DV axis *OFAS009424* was further analysed via pRNAi-mediated knockdown, but the knockdown did not result in a developmental or otherwise notable phenotype.

Bioinformatic analysis of *OFAS009424* with various tools like BLAST and Conserved Domain Search showed that the gene is highly conserved in several insect orders (Diptera, Siphonaptera, Lepidoptera, Trichoptera, Coleoptera, Hymenoptera, Phthiraptera, Hemiptera, Thysanoptera and Blattodea). *OFAS009424* putative *Drosophila* homolog *CG8646* is expressed in various tissues during embryonic development (ectoderm, posterior endoderm, Malpighian tubule, ring gland, midgut and hindgut primordia) according to various ISH screens (Tomancak et al., 2002; Tomancak et al., 2007; Lecuyer et al., 2007; Hammonds et al., 2013; Wilk et al., 2016), but has not been object of any detailed characterization or phenotypic analysis. *OFAS009424* contains the conserved domain of the ALP_like super family. This family includes alkaline phosphatases and sulfatases. Alkaline phosphatases are non-specific phosphomonoesterases that catalyze the hydrolysis reaction via a phosphoserine intermediate to produce inorganic phosphate and the corresponding alcohol, optimally at high pH. Sulfatases catalyze the hydrolysis of sulfate esters from wide range of substrates, including steroids, carbohydrates and proteins. The biological roles of sulfatases include the degradation of sulfated glycosaminoglycans and glycolipids in the lysosome and the remodeling of

sulfated glycosaminoglycans in the extracellular space. Both alkaline phosphatases and sulfatases are essential for metabolism (Peter et al., 1990; Coleman, 1992).

Figure 25: Spatial expression pattern of *OFAS009424*

(A - I) Expression pattern of *OFAS009424* revealed by ISH in *Of* late blastoderm stage wild type embryos, 24-30 hpf, anterior to the left; (A' - I') same embryo as depicted in pictures labeled with corresponding capital letters, nuclei stained with SYTOX Green; (A - C') ventral view; (D - F') ventrolateral view; (G - I') dorsal view.

3.9 Analysis of *OFAS016851*

OFAS016851 was downregulated in *Toll* and *sog* knockdown embryos compared to wild-type control embryos of *Of*. *OFAS016851* putative *Drosophila* ortholog, identified by reciprocal BLAST, is *Serp1188Ea*, a negative regulator of Toll immune signaling in the fly (Ahmad et al., 2009).

Therefore it was selected as an ISH screen candidate. The spatial expression pattern of *OFAS016851* in late blastoderm stage and early germ band stage embryos is shown in figure 26.

In late blastoderm stage embryos *OFAS016851* was expressed in an anterior cap region, encompassing about 10 to 20 % of the embryo from anterior (Fig. 26 A-A'). In invaginating germ band stage embryos *OFAS016851* was expressed in extraembryonic serosa cells (Fig. 26 B-B'). Transcript expression in the anterior cap region of blastoderm stage embryos has been reported for *tailless*, *Toll8* and *Toll10* (Weisbrod et al., 2013; Benton et al., 2016). Transcript expression in spread serosa cells has been reported for *hb*, *zen*, *Toll8* and *Toll10* (Liu and Kaufmann, 2004; Panfilio et al., 2006; Benton et al., 2016; unpublished data of M.A. Benton, Y.-T. Chen and K. H. Conrads).

Knockdown of *OFAS016851* resulted in a lethal phenotype in all observed embryos (n=183, 3 independent experiments). The phenotypic embryos did not show obvious developmental defects until enclosure. After enclosure phenotypic first instar nymphs had their mandibles and maxillae not detached from a cuticle (Fig. 27 A - B'). In contrast; antennae, labium and labrum were detached from this cuticle.

The nature of this cuticle is difficult to determine since many insect embryos including *Oncopeltus* secrete three embryonic cuticles after the serosal cuticle is secreted by the extraembryonic serosa during embryogenesis (Konopová and Zrzavý, 2005). It is not clear if the first embryonic cuticle is digested before enclosure or shed at enclosure but at least the second cuticle is shed during enclosure in many insects. The third cuticle constitutes the first instar cuticle. It is thought that those

first and second embryonic cuticles are secreted before the appendages including the mouthparts are fully elongated. Thus, the observed cuticle could be of embryonic but also serosal origin. The nature of the irregular attachment is unclear as well. It could be a pure mechanical attachment in which the mouthparts become entangled with the cuticle, possibly because the cuticle, the mouthparts or both are misshaped at their surface. Another possibility could be a chemical bounding in which the mouthparts are fused to the cuticle, possibly because of irregular overactive sclerotization. The phenotypic embryos were alive after enclosure but died within 48 h, presumably because they were disabled in their feeding abilities.

Since serosally expressed serpins are known from other insects to be involved in negatively regulating the melanization cascade (Jacobs et al., 2014), I tested if the melanization cascade in embryos in which *OFAS016851* was knocked down was overactive. I pricked both wild-type embryos and embryos lacking *OFAS016851* but I did not observe any increased melanization around the injection wound in *OFAS016851* knockdown embryos (data not shown).

Bioinformatic analysis via BLAST showed that *OFAS016851* is highly conserved in several insect orders (Diptera, Siphonaptera, Lepidoptera, Trichoptera, Coleoptera, Hymenoptera, Phthiraptera, Hemiptera, Thysanoptera and Blattodea).

Figure 26: Expression patterns of *OFAS016851*

(A - B) Expression pattern of *OFAS016851* revealed by ISH in *Of* wild type embryos, anterior to the left; **(A' - B')** same embryo as depicted in pictures labeled with corresponding capital letters, nuclei stained with SYTOX Green; **(A - A')** In blastoderm stage embryos *OFAS016851* is expressed in an anterior cap region; **(B - B')** In early germband stage embryos *OFAS016851* is expressed in the serosa.

Figure 27: *OFAS016851* RNAi defects

3.10 Analysis of *OFAS018039*

OFAS018039 was downregulated in *Toll* knockdown embryos compared to wild-type control embryos. Therefore it was selected as an ISH screen candidate. The spatial expression pattern of *OFAS018039* in late blastoderm stage embryos is shown in figure 28.

Similar to *OFAS016851* *OFAS018039* was expressed in the most anterior part of late blastoderm stage embryos. In contrast to *OFAS016851* transcript expression of *OFAS018039* was not detectable via ISH in germ band stage embryos.

Because of its asymmetric expression pattern along the DV axis *OFAS018039* was further analyzed via pRNAi-mediated knockdown, but the knockdown did not result in a developmental or otherwise notable phenotype.

Bioinformatic analysis of *OFAS018039* with various tools like BLAST, Conserved Domain Search and OrthoDB shows that the gene is conserved in several insect orders (Diptera, Siphonaptera, Lepidoptera, Coleoptera, Hymenoptera, Hemiptera, Isoptera and Blattodea). *OFAS018039* reciprocal/bidirectional best BLAST hit in *Dm* is *CG33290*, an understudied gene for which no

expression or phenotypic data is available in the literature. Conserved domains or motifs have not been identified neither for *OFAS018039* nor for *CG33290* using various bioinformatics tools.

Figure 28: Expression pattern of *OFAS018039*

(A) Expression pattern of *OFAS018039* revealed by ISH in *Of* late blastoderm stage wild type embryo, 24-30 hpf, anterior to the left; **(A')** same embryo as in A, nuclei stained with SYTOX Green; **(A - A')** in blastoderm stage *OFAS018039* is expressed in the most anterior part of the embryo.

4. Discussion

4.1 Snail is necessary for a correct formation of the opposing Sog and BMP gradients

Snail is a transcription factor and part of a conserved family of C2H2 zinc finger proteins that have been extensively studied for their role in development, cell morphogenesis, and tumor metastasis (Barrallo-Gimeno and Nieto, 2005). During early embryogenesis of *Drosophila* and *Tribolium*, the described functions of Snail are specification and internalization of the mesoderm (Simpson, 1983; Leptin and Grunewald 1990; Rao et al., 1991; Ip et al. 1994; Seher et al. 2007; von Levetzow, PhD thesis, 2008).

In *Drosophila*, *Anopheles*, *Tribolium*, *Nasonia*, *Apis* and *Oncopeltus* snail is expressed in a broad ventral domain within the presumptive mesoderm of blastoderm stage embryos (Leptin and Grunewald 1990; Buchta et al., 2013; Goltsev et al., 2007; Wilson et al., 2014; Chen, PhD thesis, 2015).

In both *Drosophila* and *Tribolium* a lack of Snail does not affect ectodermal fates but rather leads to an expansion of the mesectoderm into mesodermal territory (Leptin, 1991; Rao et al., 1991; von Levetzow, PhD thesis, 2008), consistent with Snail's function as repressor of non-mesodermal genes like *sim* (Leptin, 1991; Rao et al., 1991; Reeves and Stathopoulos, 2009).

However, the knockdown of *Oncopeltus snail* led to a derepression of the presumptive mesoderm markers *twist* and *sog*, and of the mesectodermal marker *sim* along the entire DV axis (Fig. 9), indicating a crucial difference in the mechanisms of DV axis patterning between *Oncopeltus* and other insects. A known distinctive particularity of DV axis patterning in *Oncopeltus* is that mesodermal and mesoectodermal gene expression is not strictly reliant on Toll/Dorsal signaling, as it is in other insects, but rather on the absence of BMP signaling (Sachs et al., 2015).

The temporal expression profile of *sog* during *Oncopeltus* wild-type development seems to indicate the presence of a moderate repression of *sog* within the mesoderm; in mid blastoderm stage embryos *sog* is expressed in a broad ventral stripe, but in late blastoderm stage embryos *sog* expression is moderately weakened within the presumptive mesoderm and enhanced within the mesectoderm (Sachs, PhD thesis, 2014; Chen, PhD thesis, 2015; Sachs et al., 2015). While Toll/Dorsal signaling activates *sog* expression within the mesoderm and mesectoderm (Sachs et al., 2015), Snail could moderately repress *sog* expression in the mesoderm as Snail also represses *sog* during *Drosophila* development (Reeves and Stathopoulos, 2009).

A lack of *Oncopeltus* Snail could lead to increased Sog production within the mesoderm that in turn could extend the Sog gradient to the dorsal side at the expense of the BMP gradient. A subsequent collapse of the BMP gradient and thus absence of BMP signaling along the entire DV axis would lead to a derepression of mesodermal marker genes as exposed by the *Oncopeltus dpp* knockdown (Sachs et al., 2015).

In wild-type *Oncopeltus* embryos *sim* exhibits a temporal expression dynamic similar to those of *sog*; in mid blastoderm stage embryos *sim* is expressed in a broad ventral domain, which clears ventrally during development and eventually flanks the presumptive mesoderm in narrow stripes (Yen-Ta Chen, PhD thesis, 2015). A similar temporal expression profile of *sim* was described for *Tribolium* and *Nasonia* (Buchta et al., 2013). A lack of *Oncopeltus* Snail could lead to the expansion of the mesectodermal marker *sim* into the derepressed mesoderm (Fig. 9 C), comparable to the lack of Snail

phenotypes in *Drosophila* and *Tribolium* (Leptin, 1991; Rao et al., 1991; von Levetzow, PhD thesis, 2008).

How is *Oncopeltus snail* regulated? During early development of *Drosophila* and *Tribolium snail* is activated by high levels of nuclear Dorsal and, as secondary input, by Twist (Leptin, 1991; Reeves and Stathopoulos, 2009; Stappert, PhD thesis, 2014; Stappert et al., 2016). However, the *Toll dpp* double knockdown of *Oncopeltus* seems to indicate a derepressed expression of *snail* within the expanded mesoderm as *sim* is expressed in an anterior mesectodermal domain bordering the derepressed mesoderm (Sachs et al., 2015). Thus, like *twist* and *sog*, the expression of *Oncopeltus snail* seems not to strictly rely on Toll/Dorsal signaling, but on the absence of BMP signaling.

In summary, *Oncopeltus snail* has two functions during blastoderm stage: moderate repression of *sog* within the mesoderm to buffer the self-regulatory BMP/Sog system and repression of mesectodermal genes to ensure the integrity of the mesoderm. While the second function seems to be conserved across insects, the first function seems to be a crucial element of the distinctive BMP/Sog DV axis patterning system of *Oncopeltus*.

In zebrafish, organizer-derived Bmp2b (the zebrafish homolog of Dpp) represses *chordin* transcription in the organizer and contributes to the control of the Chordin gradient (Xue et al., 2014). A lack of organizer-derived Bmp2b causes an increase of Chordin protein and transcript along the dorsoventral axis of zebrafish embryos and leads to a complete mesodermalization (Xue et al., 2014). It has been experimentally shown, that the *chordin* gene is transcriptionally repressed by Bmp/Smad signaling in zebrafish (Xue et al., 2014) and a similar mechanism was proposed for *Oncopeltus* (Sachs et al., 2015). Thus, Organizer-derived Bmp2b signaling is a mesoderm-derived source of Chordin repression which acts and is needed in parallel to the ectoderm-derived sinks of Chordin repression (e.g. cleavage by Tolloid). It seems that correct Sog/Chordin gradient formation does need both an ectodermal sink and a mesodermal impediment in both fish and bug.

4.2 New insights into BMP/Sog gradient formation extend the GRN controlling DV axis patterning in *Oncopeltus*

As phenotypic analysis revealed (see section 4.1 and Fig. 9), Snail seems to repress *sog* and *sim* within the presumptive mesoderm, while *snail* seems to be repressed by BMP signaling. The knowledge about these interactions allows extending of the GRN regulating DV axis formation of *Oncopeltus*, which was originally proposed by Sachs et al., 2015. Fig. 29 shows how the primary GRN discriminates between mesoderm and ectoderm and Fig. 30 shows how in secondary diversification the primary GRN can also pattern the mesectoderm. While the extracellular ligands of BMP signaling and the BMP antagonist Sog are diffusible components, Snail acts as immobile transcriptional repressor.

Fig. 29 Primary GRN regulating DV axis patterning in *Oncopeltus*

(A) Ventrally restricted Toll/Dorsal signaling initiates *sog* expression and thus cues the self-regulatory network. Sog forms an inhibitory complex with BMP ligands, and thus indirectly autoactivates and maintains its own expression by repression of its own inhibitor. Absence of BMP signaling is sufficient to activate *sog* and *snail* expression without any additional activator. Thus, BMP signaling transcriptionally represses both *sog* and *snail* expression and thus indirectly autoactivates itself. Expression of BMP signaling component transcripts (ligands, receptors, transcription factors) is ubiquitous, but active BMP signaling is restricted to the ectoderm by Sog inhibition. Once Sog has established its ventral expression domain by repressing BMP signaling, *snail* expression is activated. Thus, Sog indirectly activates *snail* expression, by repressing *snail*'s repressor BMP signaling. In turn, Snail transcriptionally represses *sog* expression and causes a moderate depression of *sog* transcript within the presumptive mesoderm. Through Snail's interposed position, between Sog and BMP signaling, Snail buffers the self-regulatory network and prevents an expansion of the ventral mesoderm and collapse of BMP signaling. In contrast to both Sog and BMP signaling, Snail does not autoactivate itself, but rather represses its own indirect activator Sog. Arrows indicate activation; T-bars indicate repression; black lines indicate transcriptional activation/repression; green line indicates protein-protein interaction; black text indicates individual proteins; red text indicates entire signaling pathway. **(B)** Schematic drawing of DV axis patterning in steady state, the individual concentrations of active BMP signaling, Sog and Snail are plotted on the y-axis. The x-axis shows the circumference of the embryo, with the dorsal and ventral sides marked as D and V, respectively.

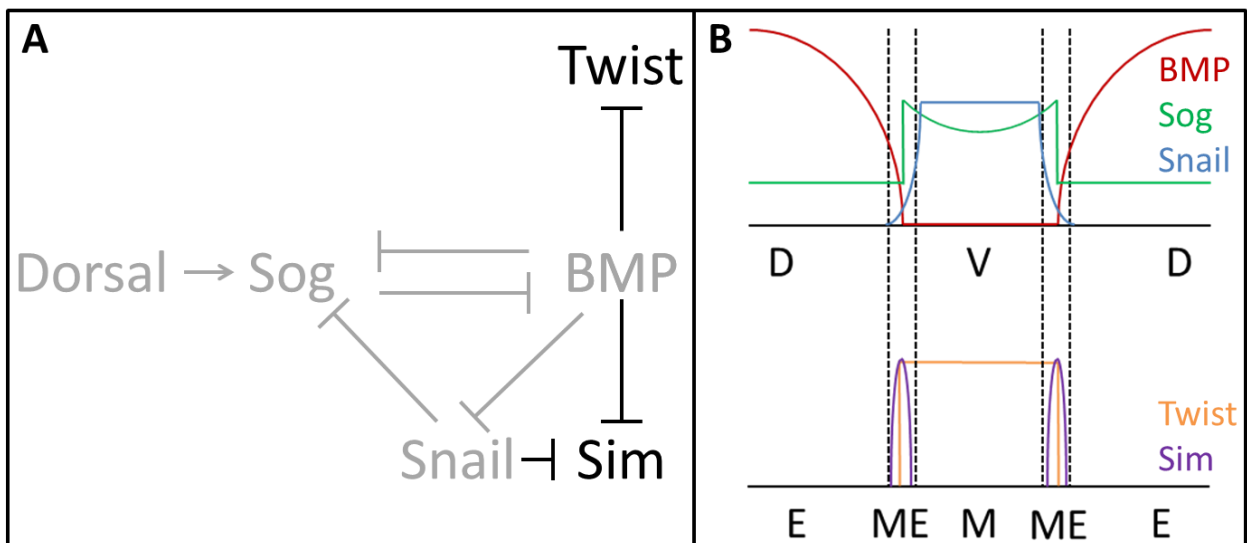

Fig. 30 GRN in secondary diversification controls mesectoderm patterning in *Oncopeltus*

(A) The primary GRN that regulates DV axis patterning in *Oncopeltus*, consisting of Dorsal, Sog, Snail and BMP signaling, is not only able to pattern the mesoderm and the ectoderm, but also the mesectoderm. The primary GRN in steady state generates a small space at the border of the mesoderm and the ectoderm in that the

concentrations of both Snail and active BMP signaling (pMad) is low. Within this space, the mesectodermal marker *sim* is expressed. Within the mesectoderm *sog* expression is not depressed by Snail, which leads to an enhancement of the lateral borders of the *sog* expression profile. The low concentration of active BMP signaling within the mesoderm and mesectoderm is sufficient to activate *twist* expression in a broad ventral domain; an input of an activator is not necessary. Arrows indicate activation; T-bars indicate repression; black lines indicate transcriptional activation/repression; black text indicates individual proteins; the primary network is grayed out for reasons of clarity and comprehensibility. **(B)** Schematic drawing of DV axis patterning in steady state, the individual concentrations of active BMP signaling, Sog, Snail, Twist and Sim are plotted on the y-axis. Top: The x-axis shows the circumference of the embryo, with the dorsal and ventral sides marked as D and V, respectively. Bottom: The x-axis shows the circumference of the embryo, with the ectoderm, mesectoderm and mesoderm marked as E, ME and M, respectively.

4.3 Microinjection of BMP4 can disturb mesoderm development

Injections with high concentrations of human BMP4 lead to a strong phenotype in which the embryo developed into a large agglutination of yolk connected with a small cuticulated part of embryonic tissue (Fig. 11). This injection phenotype is similar to the most severe *sog*, *tsg* and *dpp* knockdown phenotypes in which BMP signaling is either globally activated (*sog* and *tsg* knockdown) or suppressed (*dpp* knockdown) (Sachs, PhD thesis, 2014).

Since *Oncopeltus* embryos look uniform along their DV axis during blastoderm stage it was not possible to aim injections specifically for distinct regions along the DV axis, but on the basis of more than 150 individual injected embryos it is most likely that mesodermal as well as ectodermal regions were injected with high amounts of BMP4. However, I did not observe any phenotypic range and the observed injection phenotypes did not seem to effectively differ from each other when injected with high concentrations of BMP4 (Fig. 11). It is thus likely that due to the high abundance of ectopic BMP4, the protein diffused within the perivitelline space around the entire DV axis of injected embryos, which resulted in a uniform level of high BMP4 concentration independent of the initial site of injection. High concentrations of ectopic BMP4 most likely interfere with canonical endogenous BMP signalling by BMP4 binding to BMP receptors and extracellular BMP signaling components like Sog, Tsg and Tld. Heterodimer formation of endogenous Dpp and Gbb with ectopic BMP4 could occur as well. High uniform levels of BMP4 likely activate BMP signaling in the entire embryo which would disturb the formation of the endogenous pMad gradient and lead to an entirely symmetric pMad distribution that would lack DV polarity. The consequences of ubiquitously activated BMP signaling can be observed in strong *Toll*, *tsg* and *sog* knockdown embryos. These knockdown embryos show a complete loss of the mesoderm and mesectoderm in blastoderm and germ band stage, and gastrulation and all subsequent morphogenetic movements lack DV asymmetry (Sachs et al., 2015).

However, the observed BMP4-injection phenotype seems to be more severe than phenotypes derived from partial knockdowns of *Toll*, *tsg* and *sog* in that BMP4-injected embryos exhibit a strongly reduced and often fragmented germ band and no visible head whereas *Toll*, *tsg* and *sog* knockdown embryos often develop a head and a continuous germ band. The phenotypic severity of BMP4-injected embryos could be caused by a stronger BMP signaling activation than in partial *Toll*, *tsg* and *sog* knockdown embryos which often possess slight DV asymmetries in their pMad gradient and residual *twi*, *sog* or *sim* expression (Sachs, PhD thesis, 2014).

However, injections with moderate concentrations of BMP4 (1:10) lead to a range of milder phenotypes. Observed phenotypic traits included abnormally formed thoracic and abdominal segments, defective katarptesis and late developmental arrests after katarptesis (Fig. 12). The range

of phenotypic severity and different phenotypic traits indicates that the site of injection combined with a lower BMP4 concentration affected the phenotypic characteristics potentially by locally disturbing the canonical pMad gradient. This assumption is supported by ISH staining that show a local disturbance of mesodermal *sog* expression after BMP4 injections into mesodermal regions (Fig. 13).

Similar defects in formation of thoracic and abdominal segments are also observed in *sog* or *tsg* knockdown phenotypes and could be caused by a local dorsalization of such segments in BMP4 injected embryos. Defective katanatresis is observed in many knockdown phenotypes of genes with dorsalizing and ventralizing effects like *sog*, *tsg*, *tld* and *dpp* (Sachs, PhD thesis, 2014). Katanatresis is dependent on a functional amnion in *Oncopeltus* (Panfilio et al., 2006). It is assumed that the amnion anlage is located dorsally in the early *Oncopeltus* embryo and that the correct development of the amnion is dependent on a canonical pMad gradient (Sachs, PhD thesis, 2014). Defective formation of the amnion caused by a globally disturbed pMad gradient like in strong *sog*, *tsg*, *tld*, *dpp* and *gbb* knockdown phenotypes or a locally disturbed pMad gradient like in *Oncopeltus* embryos injected with BMP4 in moderate concentrations is likely to be the reason for defective katanatresis.

Although BMP4-injection phenotypes are comparable to pRNAi-mediated *sog* and *tsg* knockdown phenotypes they do not phenocopy each other. On the one hand pRNAi mediated gene knockdown implemented in virgin females affects already oogenesis and, from the very beginning, embryogenesis whereas microinjections of proteins or mRNA implemented at 24 – 30 hpf can only affect embryogenesis from this point onwards. Shallow pMad gradients can already be detected around 26 hpf in wild-type embryos although cell fates are not fixed unalterably during blastoderm stage in the self-organizing DV patterning system of *Oncopeltus* (Sachs et al., 2015). On the other hand especially microinjections at moderate concentrations affect embryogenesis rather local, spatially dependent on the site of injection, whereas pRNAi affects embryogenesis on a global level.

4.4 An ectopic source of *chordin* induces mesodermal cell fates independent of Toll

Microinjections of *chordin* into both dorsalized Toll knockdown embryos and into the dorsal side of *Oncopeltus* wild-type embryos induced the expression of the ventral marker genes *sim*, *sog* and *twist* and mesoderm-like nuclear density patterns (Fig. 18 - 22). Thus, a local depression of BMP signaling induces ventral cell fates even in a BMP dominated background that lacks endogenous Toll/Dorsal signaling.

However, the injection-induced domains of ventral marker transcript expression suggest a fading over time resulting in a transition from patch-like to ring-like domains which suggests that the ectopic mesodermal domain tends to be instable and seems to decompose and become ectodermal again (Fig. 18 - 22). If the ventral marker gene expression within such rings has entirely faded, accordingly nuclear density increases to ectodermal levels again, which further indicates the instability of the injection-induced mesodermal domains and their tendencies to decompose and become ectodermal again (Fig. 18).

As phenotypic analysis suggests *snail* is a crucial component of the BMP/Sog system of *Oncopeltus* (see section 4.1, 4.2 and Fig. 9). The GRN incorporating Snail shows, that Sog indirectly activates its own inhibitor *snail* (Fig. 29). Such an activation of *snail* within the injection-induced mesodermal domain, subsequent repression of *sog* and thus, reactivation of BMP signaling can explain a transition from mesodermal to ectodermal fates. The observed “patch-within-ring” patterns (Fig. 9 C) can be explained as well with the same GRN; once Snail has repressed *sog* and BMP signaling gained

dominance again, in turn, BMP signaling represses *snail* and thus, *sog* becomes activated again. Apparently the self-regulatory network cannot enter steady state but oscillates between Sog/mesoderm and BMP/ectoderm dominance. Within the endogenous mesoderm in *Oncopeltus* wild-type embryos a continuous activation of *sog* by Toll/Dorsal signaling could prevent such oscillation and facilitate steady state establishment.

4.5 OFAS016851 and OFAS018039 are potential serosa markers

OFAS016851 and *OFAS018039* are expressed in the early embryo at blastoderm stage in the anterior cap and *OFAS016851* is additionally expressed later during germ band stage in spreading serosa cells (Fig. 26 and 28). It has been proposed before that the regions of the blastoderm stage embryo of *Oncopeltus* that do not express *engrailed*, namely the anterior cap and the most dorsal part of the embryo, could be presumed as extraembryonic territories (Liu and Kaufman, 2004; Panfilio et al., 2006). The expression pattern of *OFAS016851* indeed seems to suggest that the presumptive serosa is patterned in the anterior cap of *Oncopeltus* blastoderm stage embryos.

However, work from the Chipman lab shows that in blastoderm stage embryos *tailless* is expressed in the anterior cap region. As the blastoderm starts to invaginate at the posterior the expression of *tailless* refines to a pair of lateral patches while the most anterior 10 % stop to express *tailless*. In developing germ bands *tailless* is expressed in the head lobes. In embryos that lack *Tailless* the head lobes including the eyes are missing (Weisbrod et al., 2013). It is possible that during early blastoderm stage *tailless* and *OFAS016851* are coexpressed and that their expression refines and splits shortly before or at the onset of the posterior blastoderm invagination into the yolk and the anterior serosa expansion on top of the yolk.

Both *OFAS016851* and *OFAS018039* could turn out to be useful serosa markers, especially *OFAS016851* since it is expressed not only in blastoderm stage but also in spreading serosa cells.

It has been proposed before that from the anterior region of the early *Oncopeltus* egg the presumptive serosa emerges whereas the amnion is thought to emerge from the most dorsal part of the embryo itself (Panfilio et al., 2006). Similar fate maps in which the serosa emerges anterior of the condensing germ band are realized in hemimetabolous insects like *Schistocerca* (Dearden et al., 2000) and potentially *Gryllus* (Nakamura et al., 2010) and this architecture could be a plesiomorphic character. In contrast, in insects of most major holometabolous orders like hymenoptera (*Apis* and *Nasonia*), lepidoptera (*Bombyx*), coleopteran (*Tribolium*) and diptera (*Drosophila*, *Megaselia* and *Anopheles*) the anlage of the serosa and amnion or the amnioserosa, respectively, seems to have a derived position within the embryonic fate map (Amanai et al., 1994; van der Zee et al., 2005; Goltsev et al., 2007; Rafiqi et al., 2008; Rafiqi et al., 2012; Panfilio, 2008; Buchta et al., 2013; Wilson et al., 2014).

4.6 OFAS016851 RNAi phenotype

Oncopeltus embryos in which *OFAS016851* was knocked down died within 48 h after enclosure, presumably because their mandibles and maxillae were not detached from their embryonic cuticles, which seemed to disable them from feeding (Fig. 27). *OFAS016851* codes for a member of the serpin family. The serpin gene family is the largest family of protease inhibitors, present in animals, plants,

bacteria, archea and poxviruses (Law et al., 2006). The majority of serpins inhibits serine proteases. Serpins are central in controlling many proteolytic cascades including the blood clotting cascade, the protease cascade upstream of Toll and Toll-like receptors and the cascade which proteolytically activates many phenoloxidases, which are involved in melanization and sclerotization (De Gregorio et al., 2002; Ligoxygakis et al., 2003; Zou et al., 2005; Rau et al., 2007; Scherfer et al., 2008; Tang et al., 2008).

It is difficult to speculate about the causes of the *OFAS016851* knockdown phenotype. First, the nature of the irregular attachment of the mouthparts to the cuticle is unknown. Second, it is unknown if the cuticle is of serosal or embryonic origin. Third, the role of serpins is diverse and several distinct functions of various serosal serpins are described. Serosally expressed serpins are thought to function in immunity by regulating Toll signaling and the melanization cascade, and in wound healing also by regulation of the melanization cascade (Jacobs et al., 2014). However, loss of these functions cannot explain the phenotype. Besides providing immunity and wound healing capacities the serosa secretes the serosal cuticle which provides desiccation resistance (Jacobs et al., 2013). The mechanical properties of cuticles are determined by the interplay of many factors including the degree of sclerotization (Arakane et al., 2005; Andersen, 2010). Central players in sclerotization are phenoloxidases which are proteolytically activated by serine protease cascades which in turn are negatively regulated by serpins (Kanost and Gorman, 2008). Overactive sclerotization of serosal or embryonic cuticles caused by a lack of *OFAS016851* could possibly explain the attachment of mouthparts to cuticle.

OFAS016851 *Drosophila* ortholog *Serpin 88Ea* was determined via bidirectional BLAST. Carron and colleagues report, that in *Drosophila* *Serpin 88Ea* is expressed in ovaries, at all embryonic stages except between five and fifteen hours of development, throughout larval and pupal development and in adults. Homozygous mutant lines for *Serpin 88Ea* are not viable. However, heterozygous lines are viable and RNAi silencing turned out to be difficult in that several RNAi transgene copies were needed to achieve a detectable decrease of *Serpin 88Ea* mRNA levels. The only conspicuous phenotype that was observed following RNAi-mediated perturbation of *Serpin 88Ea* expression was a defect in wing development, specifically in the unfolding and expansion of the wings (Charron et al., 2008). Interestingly, the few *Spn27A* deficient flies that enclose also show a defect in wing expansion (De Gregorio et al., 2002). It seems that there are many redundancies and shared functions between the different serpins, yet many knockouts of single serpins are lethal.

Outlook

As the integration of Snail into the BMP/Sog system of *Oncopeltus* leads to an extended GRN for DV axis patterning, it is of great interest to simulate the new GRN *in silico* to test if it can pattern mesoderm, ectoderm and mesectoderm as hypothesized. Another important experiment would be the detection of *snail* transcripts via ISH in *Toll* and *dpp* single knockdowns as well as in the *Toll/dpp* double knockdowns as the repression of *snail* by BMP signaling is not shown directly, but rather hypothesized by phenotypic analysis. In addition, the expression of *snail* in *chordin*-injected wild-type and *Toll* knockdown embryos should be detected by ISH and analyzed as well, together with the expression of *sim* in *chordin*-injected wild-type and *twist* in *chordin*-injected *Toll* knockdown embryos. However, the detection of *snail* transcripts around the site of *chordin*-injection might be hard to realize; as soon as Snail is synthesized it will repress *sog* and facilitate BMP signaling and thus repress its own transcription.

Another interesting experiment would be to generate *Toll/snail* double knockdown embryos and analyze their fate map, as it is not clear how the GRN would perform in such a background. A *Toll/snail* double knockdown could potentially phenocopy a *Toll/dpp* knockdown (except expansion of mesectodermal markers into the derepressed mesoderm).

However, a *Toll/snail* double knockdown could also phenocopy a *dpp* knockdown, as the BMP network would lack a polarization via Toll that is needed to express *sog* within a BMP-rich background. If this would be the case, *chordin*-injections into *Toll/snail* double knockdown embryos could lead to a stable induction of ectopic mesodermal domains or even an entire collapse of BMP signaling in line with derepression of mesodermal fates along the entire DV axis.

Finally, as new version of the *Oncopeltus* genome is to be released, mapping of the RNAseq reads to the latest *Oncopeltus* official gene set could potentially increase the RNAseq analysis by a large magnitude.

Appendix

This appendix includes the output of the RNAseq analysis (see section 3.7 and Fig. 24) as tables in which the various transcriptomes of different knockdown conditions are compared to wild-type embryos. Green marks indicate upregulation compared to wild-type, red marks indicate downregulation compared to wild-type.

Table 5.: *Toll* knockdown compared to wild-type embryos

Danksagungen

Zuerst möchte ich Prof. Dr. Siegfried Roth für die Möglichkeit danken diese Arbeit in seinem Labor bearbeiten zu dürfen. Bedanken möchte ich mich außerdem bei ihm für die ausgezeichnete Betreuung und die anregenden Hilfestellungen.

Herrn Prof. Dr. Matthias Hammerschmidt möchte ich Danken für das Erstellen des Zweitgutachtens.

Großer Dank gebührt auch Dr. Nathan J. Kenny für die großartige Hilfestellung bei der Durchführung der Transkriptomanalyse.

Bedanken möchte ich mich außerdem bei der AG von Prof. Dr. Matthias Hammerschmidt für die freundliche Zurverfügungstellung Ihres Zebrafisch *cordin* Plasmiden.

Dr. Kristen Panfilio möchte ich danken für das Teilen Ihrer Erfahrung über die Embryogenese und die experimentelle Arbeit von und mit *Oncopeltus fasciatus*.

Dr. Matthias Pechmann und Dr. Matthew A. Benton möchte ich danken für die extrem wertvollen Diskussionen über die Laborarbeit im Allgemeinen und unzähligen Hilfestellung bei diversen experimentellen Herausforderungen.

Dr. Lena Sachs und Dr. Yen-Ta Chen möchte ich danken für die Einführung in die experimentelle Laborarbeit mit *Oncopeltus fasciatus*.

Ich möchte mich ganz herzlich bedanken bei Dr. Nadine Frey, Dr. Daniela Gurská und Dr. Muhammad Salim Hakeemi für die gemeinsam verbrachte Zeit im Büro Und Labor, sowie bei den unendlich vielen Hilfestellungen während meiner gesamten Promotionszeit.

Dank gebührt auch Oliver Karst für die Zusammenarbeit im Büro und Labor während der gesamten Promotion.

Ich danke natürlich auch meiner gesamten Familie und all meinen Freunden die mich im Verlauf der Promotion bedingungslos unterstützt haben. Mein größter Dank gilt meinem Sohn Finn für das Lächeln das er mir jeden Tag schenkt.

Erklärung zur Dissertation

Ich versichere, dass ich die von mir vorgelegte Dissertation selbständig angefertigt, die benutzten Quellen und Hilfsmittel vollständig angegeben und die Stellen der Arbeit – einschließlich Tabellen, Karten und Abbildungen –, die anderen Werken im Wortlaut oder dem Sinn nach entnommen sind, in jedem Einzelfall als Entlehnung kenntlich gemacht habe; dass diese Dissertation noch keiner anderen Fakultät oder Universität zur Prüfung vorgelegen hat; dass sie – abgesehen von unten angegebenen Teilpublikationen – noch nicht veröffentlicht worden ist, sowie, dass ich eine solche Veröffentlichung vor Abschluss des Promotionsverfahrens nicht vornehmen werde. Die Bestimmungen der Promotionsordnung sind mir bekannt. Die von mir vorgelegte Dissertation ist von Prof. Dr. Siegfried Roth betreut worden.

Teilpublikationen: keine

(Ort, Datum)

(Kai Hans Conrads)

Lebenslauf

Persönliche Informationen

Name: Kai Hans Conrads
Geburtstag: 29. September 1987
Geburtsort: Neuss
Nationalität: deutsch

Schulbildung

07/1994 – 07/1998 Albert-Schweizer-Grundschule, Neuss
08/1998 – 07/2007 Abitur am Gymnasium Norf, Neuss

Zivildienst

08/2007 – 07/2008 Träger: Lebenshilfe Rhein-Kreis Neuss

Studienverlauf

07/2008 – 07/2012 B.Sc. in Biologie an der Universität zu Köln
Thesis: „Analysis of Fog signaling in *Nasonia vitripennis*“
10/2012 – 09/2015 M.Sc. in Biologie an der Heinrich-Heine-Universität Düsseldorf
Thesis: „Embryonic patterning in the bean beetle *Callosobruchus maculatus*“

Promotion

Seit 10/2015 Promotion an der Universität zu Köln
Institut für Entwicklungsbiologie
Betreuer: Prof. Dr. Siegfried Roth

Beruflicher Werdegang

Seit 06/2021 klinischer Monitor bei IQVIA RDS GmbH
