Dekan: Universitätsprofessor Dr. med. G. R. Fink

1. Gutachter: Professor Dr. med. P. Baradaran Rahmania
2. Gutachter: Universitätsprofessor Dr. med. S. Baldus
3. Gutachter: Professor Dr. R. Zimmermann

Erklärung:

Ich erkläre hiermit, dass ich die vorliegende Dissertationsschrift ohne unzulässige Hilfe Dritter und ohne Benutzung anderer als der angegebenen Hilfsmittel angefertigt habe; die aus fremden Quellen direkt oder indirekt übernommenen Gedanken sind als solche kenntlich gemacht.

Bei der Auswahl und Auswertung des Materials sowie bei der Herstellung des Manuskriptes habe ich Unterstützungsleistungen von folgenden Personen erhalten:

Herr Dr. K. Dhaygude
Herr Dr. M. Saraswat
Herr S. Joenvääri
Herr Dr. med. S. Syrjälä
Herr Dr. med. E. Holmström
Herr Dr. R. Krebs
Frau E. Rouvinen
Herr Dr. med. A. Nykänen
Herr Professor R. Renkonen
Herr Professor K. Lemström

Weitere Personen waren an der Erstellung der vorliegenden Arbeit nicht beteiligt. Insbesondere habe ich nicht die Hilfe einer Promotionsberaterin/eines Promotionsberaters in Anspruch genommen. Dritte haben von mir weder unmittelbar noch mittelbar geldwerte Leistungen für Arbeiten erhalten, die im Zusammenhang mit dem Inhalt der vorgelegten Dissertationsschrift stehen.

Die Dissertationsschrift wurde von mir bisher weder im Inland noch im Ausland in gleicher oder ähnlicher Form einer anderen Prüfungsbehörde vorgelegt.

Die dieser Arbeit zugrunde liegende Konzeptualisierung und Forschungsfinanzierung wurde mit meiner Mitarbeit von Herr Dr. med. A. Nykänen, Herr Professor K. Lemström und Herr Professor R. Renkonen durchgeführt.

Das dieser Arbeit zugrunde liegende Forschungsdesign wurde mit meiner Mitarbeit von Herr Dr. med. A. Nykänen, Herr Professor K. Lemström, Herr Dr. K. Dhaygude und Herr Professor R. Renkonen erstellt.

Der dieser Arbeit zugrunde liegende Datensatz wurde mit meiner Mitarbeit an der Universitätsklinik Helsinki in Finnland in der Abteilung für Herz- und Thoraxchirurgie und im Transplantationslaboratorium von Herr Dr. med. A. Nykänen, Herr Dr. med. S.

Syrjälä, Herr Dr. K. Dhaygude, Herr S. Joenväärä, Herr Dr. M. Saraswat, Herr Dr. med. E. Holmström, Herr Dr. R. Krebs und Frau E. Rouvinen erhoben. Dabei wurden die Plasmaproben von Herr Dr. R. Krebs und Frau E. Rouvinen gesammelt, aufbereitet und gelagert, das Proteom der Plasmaproben von Herr S. Joenväärä und Herr Dr. M. Saraswat bestimmt und von Herr Dr. K. Dhaygude und mir statistisch analysiert. Die klinischen Daten wurden von Herr Dr. med. A. Nykänen, Herr Dr. med. S. Syrjälä, Herr Dr. med. E. Holmström und mir zusammengetragen und statistisch analysiert.

Die dieser Arbeit zugrunde liegenden analytischen Methoden wurden mit meiner Mitarbeit von Herr Dr. med. S. Syrjälä, Herr Dr. M. Saraswat, Herr Dr. K. Dhaygude und Herr Professor R. Renkonen eingebracht.

Die dieser Arbeit zugrunde liegende Datenanalyse wurde mit einer Mitarbeit von Herr Dr. K. Dhaygude, Herr Dr. med. S. Syrjälä, Herr S. Joenväärä und Herr Dr. M. Saraswat durchgeführt. Dabei wurde die Flüssigchromatographie mit Massenspektrometrie-Kopplung von Herr S. Joenväärä und und Herr Dr. M. Saraswat, die Statistik-Programmiersprache RStudio von Herr Dr. K. Dhaygude und die Statistiksoftware SPSS von Herr Dr. med. S. Syrjälä und mir verwendet. Zusätzlich wurde die IPA Canonical Pathway Analysis-Software von mir verwendet.

Die dieser Arbeit zugrunde liegenden Ergebnisse wurde mit meiner Mitarbeit von Herr Dr. med. A. Nykänen, Herr Dr. K. Dhaygude, Herr Dr. M. Saraswat, Herr Dr. med. S. Syrjälä, Herr S. Joenväärä und Herr Professor K. Lemström interpretiert.

Die dieser Arbeit zugrunde liegende Publikation wurde mit meiner Mitarbeit von Herr Dr. med. A. Nykänen, Herr Dr. K. Dhaygude, Herr Dr. med. S. Syrjälä, Herr Dr. M. Saraswat, Herr S. Joenväärä, Herr Dr. R. Krebs und Herr Professor K. Lemström verfasst.

Erklärung zur guten wissenschaftlichen Praxis:

Ich erkläre hiermit, dass ich die Ordnung zur Sicherung guter wissenschaftlicher Praxis und zum Umgang mit wissenschaftlichem Fehlverhalten (Amtliche Mitteilung der Universität zu Köln AM 132/2020) der Universität zu Köln gelesen habe und verpflichte mich hiermit, die dort genannten Vorgaben bei allen wissenschaftlichen Tätigkeiten zu beachten und umzusetzen.

Järvenpää, den 23.05.2023

Unterschrift: 

Danksagung

Mein Dank gilt meinem Doktorvater Prof. Dr. Parwis Rahmanian für die Betreuung dieser Dissertationsarbeit und die zugewandte und freundliche Unterstützung. Zudem möchte ich mich bei dem Transplantationslabor der Universität Helsinki für die fruchtbare Zusammenarbeit und bei der Medizinischen Fakultät zu Köln für die Möglichkeit des Medizinstudiums sowie die Unterstützung während des Studiums und des Dissertationsvorhabens bedanken. Darüber hinaus gilt ein großer Dank meiner Lebensgefährtin Ella für ihre unentwegte Unterstützung.

1. SUMMARY IN GERMAN

Die Herztransplantation ist die Therapie der Wahl für Patienten mit terminaler Herzinsuffizienz aus verschiedenen Gründen. Aufgrund der Alterung der Gesellschaft steigt die Zahl an Patienten, die ein Spenderherz benötigen, während gleichzeitig die Zahl an geeigneten Spenderherzen sinkt. Um den daraus entstehenden und stetig wachsenden Organmangel entgegenzuwirken, wird zunehmend auf marginale Spenderorgane zurückgegriffen. Jedoch führt die Verwendung dieser Organe mit eingeschränkter Qualität zu einem häufigeren Auftreten von primären Transplantatversagen und einer verkürzten Überlebenszeit.¹ Dabei werden auftretende Komplikationen der Spenderorgane häufig zu spät diagnostiziert und deren Ätiologie bleibt nur unzureichend bekannt und geklärt.

Um eine optimierte Verwendung von Spenderherzen zu erreichen, ist es von großer Wichtigkeit Spenderherzen mit einem erhöhten Risiko für Transplantatversagen frühzeitig zu identifizieren und die Behandlung entsprechend anzupassen. Jedoch ist hierfür ein verbessertes Verständnis der zugrundeliegenden molekularen Pathophysiologie vonnöten. Ein vielversprechender Ansatz für die Erforschung der molekularen Pathologie stellt die Proteomik dar. Unter Proteomik versteht man die Erforschung des Proteoms mit biochemischen Methoden. Das Proteom umfasst die Gesamtheit der Proteine in einer Zelle, einem Organ oder eines Organismus. So kann durch die Verwendung der Liquid-Chromatographie Massenspektrometrie/Massenspektrometrie (LC-MS/MS) auf der Proteinebene ein detaillierter Einblick in die Pathophysiologie und die molekularen Fingerabdrücke von Spenderorganen mit einer schlechteren klinischen Prognose gewonnen werden.

In dieser retrospektiven monozentrischen Studie, die an der Universitätsklinik Helsinki durchgeführt wurde, wurden Plasmaproben von 54 hirntoten Organspendern sowie 24 gesunden Kontrollprobanden im Zeitraum von 2010 bis 2016 gesammelt und in Hinblick auf einen möglichen Einfluss auf das Ergebnis nach Herztransplantation hin untersucht. In der anschließenden Ultra-Performance-Flüssigchromatographiegekoppelten Tandemmassenspektrometer (UPLC-MS/MS) Analyse der Plasmaproben wurden insgesamt 463 Proteine identifiziert. Als Nächstes wurden mithilfe von uni- und multivariaten Analysen die Unterschiede in der Proteinexpression zwischen den Organspendern und den gesunden Kontrollprobanden untersucht. Von 463 Proteinen waren 237 Proteine unterschiedlich zwischen den beiden Gruppen exprimiert, wobei 90 Proteine eine verminderte und 149 eine erhöhte Expression in den Organspendern zeigten. Für die Erforschung der zugrundeliegenden biologischen Mechanismen wurde die Pathway-Enrichment-Analyse angewendet. Es wurden 6 Pathways gefunden von denen Glukoneogenese, Glykolyse und Koagulation in den Organspendern hochreguliert, und Komplementsystem, LXR/RXR-Aktivierung und Produktion von Stickstoffmonoxid und reaktiven Sauerstoffspezies in Makrophagen herunterreguliert waren. Um potenzielle Biomarker für ein negatives Outcome zu finden, wurde die Assoziation zwischen dem Plasmaproteom der Organspender und den klinischen Endpunkten der Organempfänger wie primäres Transplantatversagen, akute Abstoßungsreaktion mit hämodynamischer Instabilität, sowie transplantatbedingte Sterblichkeit analysiert. In punktbiserialer Korrelationsanalyse war das Protein *Lysine-specific demethylase 3A* moderat mit dem Auftreten von jeglichen und schweren primären Transplantatversagen assoziiert. In der uni- und multivariaten Cox-Regressionsanalyse wurden *Myosin Va* und *Proteasome activator complex subunit 2* als Prädiktoren für die Entstehung einer akuten Abstoßungsreaktion mit hämodynamischer Instabilität innerhalb von 30 Tagen identifiziert. In der

univariaten Analyse war eine erhöhte Expression von *Lysine-specific demethylase 3A* and *Moesin* mit einer erhöhten transplantatbedingten 1-Jahres-Sterblichkeit vergesellschaftet.

Unsere Ergebnisse zeigen, dass der Hirntod eine signifikante Auswirkung auf das Plasmaproteom der Organspender hat. Das Proteinprofil der Organspender ist charakterisiert u.a. durch Dysregulation von Blutgerinnung, Komplementsystem, Immunsystem, sowie Verletzung des Endothels und Myokardiums. Wir haben Plasmaproteine gefunden, die mit dem klinischen Ergebnis nach Herztransplantation assoziiert sind. Diese Proteine stellen womöglich potenzielle Biomarker dar, die dabei helfen könnten Spenderorgane mit einem erhöhten Risiko für Komplikationen bereits vor der Transplantation zu identifizieren und das weitere Management von Organspender, Spenderorgan und Organempfänger zu optimieren.

2. INTRODUCTION

Heart transplantation (HTx) is the only curative treatment for patients with end-stage heart failure that cannot be managed with maximum medical therapy. Annually, around 8000 HTx are performed worldwide, out of which around 20 HTx are performed in Finland, and around 329 in Germany.^{2,3,4} Heart transplants come either from donation after brain death or donation after circulatory death. Despite recent advances in donation after circulatory death, donation after brain death remains the mainstay of heart transplantation. However, brain death causes progressive and detrimental tissue damage in the central nervous system leading to massive circulatory, hormonal, and metabolic changes and systemic inflammation. This may expose donor organs to injury and increase the risk of acute rejection, primary graft dysfunction (PGD), and mortality in heart transplant recipients.^{5,6,7,8} However, the molecular mechanisms and pathways affecting donor organ quality in brain-dead organ donors are still not fully understood and studies have relied on examining clinical parameters, donor demographics, and a small number of proteins such as *Donor B-type natriuretic peptide*.^{9,10}

Currently, most heart transplants are retrieved from brain-dead multiple organ donors and clinical outcomes have markedly improved over the decades.¹¹ Nevertheless, PGD is an early postoperative complication that occurs in up to 28 to 36% of cases and is still the leading cause of early mortality, accounting for about 43% of deaths that occur within 30 days after HTx.^{12,13,14} PGD-related mortality within 30-days is up to 19% compared to 4.5% all-cause mortality in patients without PGD.¹⁵ Long-term PDG-related mortality has been reported to be up to 42% compared to 8% all-cause mortality in patients without PGD.¹⁶ The International Society for Heart and Lung Transplantation (ISHLT) established the diagnostic and grading criteria for PGD in a

consensus statement in 2014.¹⁷ PGD is defined as the presentation of left, right, or biventricular dysfunction occurring within the first 24 hours after HTx. Additionally, other secondary causes of graft dysfunction such as hyperacute rejection, pulmonary hypertension, or known surgical complications must be ruled out. Left ventricle PGD can be further categorized into mild, moderate, or severe PGD. The severity of PGD is determined based on ejection fraction, hemodynamics, and the need for inotropic or mechanical support. Risk factors for the development of PGD include donor, recipient, and procedural factors. Donor factors include inter alia age and the cause of brain death. Recipient factors encompass overweight, diabetes, and pre-operative inotropic and mechanical circulatory support. Procedural factors include donor heart ischemic time, donor-recipient weight mismatching, and cardiopulmonary bypass time.^{18,19,20,21,22,23} However, not all risk factors of PGD are known, and underlying molecular processes have not been fully explained. Such multifactorial etiology complicates the diagnostic evaluation and makes it difficult to distinguish between heart transplant patients with a high risk of PGD on the one hand and patients with a low risk on the other hand.

The ongoing shortage of heart organ donors is a major limiting factor for heart transplantation. Organ shortage is aggravated by population aging which leads to an increasing number of patients with end-stage heart failure on the organ waiting list while the number of older donors with comorbidities and lower organ quality is growing.²⁴ To extend the donor organ pool, more clinicians accept marginal donors for transplantation. Marginal donors are suboptimal donors who do not meet the criteria of an optimal donor. It is generally accepted that an optimal donor can be characterized amongst others by a maximum age of 55 years, absence of left ventricular hypertrophy, ischemic time of less than 4 hours, suitable donor to recipient predicted heart mass

ratio, having no coronary artery disease, no history of alcohol abuse, and gender-matched transplantation.^{25,26,27,28,29,30} However, the increased use of marginal donors is complicated by the fact that marginal donors have a higher risk of transplant failure including the occurrence of PGD as well as death.^{31,32} Therefore, it is important to further investigate the effect of known and unknown risk factors on the clinical outcome of marginal heart donors.

As brain death has specific implications for the heart transplant quality and the use of marginal donors with higher risk of complications is increasing, making efforts to prevent and minimize acute rejection, PGD, and mortality are of immense importance. However, a thorough understanding of the pathophysiology in brain-dead organ donors at the molecular level is needed. Based on the investigation and improved understanding of molecular mechanisms and pathways, novel biomarker candidates could be discovered. So far, clinical biomarkers to detect and monitor the quality of transplants in human brain-dead donors are unavailable. Liquid biopsies based on plasma samples may offer the possibility to identify heart transplants with lower quality and an increased risk of transplant failure. Early detection of high-risk transplants could lay the basis for improved management of the heart transplant during procurement, preservation, reperfusion, transplantation, and post-transplant treatment.

The underlying molecular level of pathophysiology can be investigated with different omics-based methods such as genomics, miRNA omics, and proteomics. Using proteomics with ultra-high-performance liquid chromatography, connected to tandem mass spectrometry (UPLC-MS/MS), offers a promising approach to accurately measure the protein expressions in plasma. Furthermore, proteomics can be embedded in a systemic biology approach to ease the systemic characterization of

plasma proteins.³³ Uni- and multivariate statistical analyses can be used to find significant differences in protein expression between two groups. Next, biological pathway analyses and literature research pinpoint modulated key proteins, pathways, and biological mechanisms, and therefore help to elucidate the complex pathophysiology of brain-dead organ donors.³⁴

In this study, a label-free proteomics approach was used to reveal the plasma proteomic profile of brain-dead organ donors. We sought to find key proteins, biological pathways, and pathogenic mechanisms that are affected by the brain death of organ donors. Moreover, we aimed to enhance the understanding of the complex unphysiological state of brain-dead donors and to search for novel biomarker candidates for the risk evaluation of cardiac donor organs.

3. MATERIAL AND METHODS

This study is a post hoc analysis of multi-organ donors participating in a prospective, randomized clinical trial on the effects of donor simvastatin treatment on ischemia-reperfusion injury after heart transplantation (Nykänen et al.) Nykänen et al. included heart transplantations performed at Helsinki University Hospital between 2010 and 2016 unless they did not meet the inclusion criteria. 84 heart donors were randomly assigned to receive 80 mg of simvastatin (42 donors) via nasogastric tube within 2 hours after the declaration of brain death or to receive no simvastatin (42 donors). They found that donor treatment with simvastatin reduces biomarkers of myocardial injury and heart failure as well as the number of acute rejections with hemodynamic compromise early after heart transplantation.³⁵ Out of the original 84 trial donors and recipients, 54 donor samples were chosen for proteomics analysis as they had complete sets of all time points samples available of the donor and recipient pair (1h to 24h). Out of 54 donor samples, 27 donors belonged to the simvastatin treatment group. In addition to the 54 donor samples, control samples were collected from 24 healthy controls. Next, we analyzed the 54 donor and 24 plasma protein samples by nano ultra-high-performance liquid chromatography and quantified them with UPLC-MS/MS before we compared the plasma proteome with clinical outcome after HTx.

The study was reviewed and approved by the Institutional Ethical Committee of the Helsinki University Hospital (Permission 358/13/03/02/2009 amendment), Helsinki, Finland. The Institutional Review Board concluded that consent would not be required for the use of samples collected after the declaration of brain death. Control samples from healthy volunteers were obtained from employees of the research institute. The

study was carried out adhering to the International Conference on Harmonization E6 guidelines for Good Clinical Practice and the principles of the Declaration of Helsinki.

Heart transplant donors with the following criteria were excluded from the study: >60 years of age, located outside of Finland, low left ventricular ejection fraction (ejection fraction <45%), severe left ventricular hypertrophy (posterior wall or septal thickness >14 mm), abnormal coronary angiography requirement of high-dose inotropic agent treatment at organ procurement (dopamine or dobutamine >20 ugs/kg/min or norepinephrine >0.2 ugs/kg/min), or previous statin drug treatment. At least one echocardiogram was acquired from all donors and coronary angiogram was performed in donors with the age of >40 years, a strong family history of coronary artery disease, or a smoking history. Clinical donor management and follow-up were carried out based on the clinical protocol of the Heart and Lung Transplantation Program at the Helsinki University Hospital.³⁶ Immediately after the declaration of brain death, donors received 1g of methylprednisolone and 1g of meropenem intravenously.

Plasma samples were taken by employees of the transplantation laboratory and collected in lithium heparin tubes before heparinization and organ procurement. After cooling down, we used the "Top 12 Abundant Protein Depletion kit" (Pierce, Thermo Fisher) to deplete greater than 95% of the most abundant proteins from 10 µl of plasma. The list of 12 depleted proteins included *alpha-1-acid-glycoprotein*, *alpha-1-antitrypsin*, *alpha-2-macroglobulin*, *albumin*, *apolipoprotein A-I*, *apolipoprotein A-II*, *fibrinogen*, *haptoglobin*, *IgA*, *IgG*, *IgM*, and *transferrin*, and the remaining proteins were digested by trypsin. In addition, donor hemoglobin (Hb), platelets, hsTnT, hsTnI, CRP, total cholesterol, high-density lipoprotein, low-density lipoprotein, and triglycerides were analyzed from plasma samples by an accredited clinical laboratory (HUSLAB,

Helsinki University Hospital). UPLC-MS/MS was performed as described.³⁷ Label-free quantification failed on 1 donor sample due to the batch effect, therefore this sample was excluded from the study. One control sample failed normalization and was removed from the study. Therefore, finally 53 donor and 23 control samples were considered for subsequent statistical analysis.

In statistical analyses, unsupervised PCA and SOM and supervised OPLS-DA modeling methods were applied to illustrate the clustering of all 463 quantified proteins. Grouping patterns, trends, and outliers were examined on scatter plots and heatmap. We used the `ropls` and `pheatmap` packages in R software. Next, we performed univariate and multivariate analyses to find differentially expressed proteins between donors and healthy controls. First, we performed univariate analysis on all 463 quantified proteins including the Wilcoxon-Mann-Whitney test, fold change analysis, and the S-Plot for OPLS-DA. Wilcoxon-Mann-Whitney test p value was corrected using the Benjamini-Hochberg method and an FDR-corrected p value of <0.05 was considered significant. Multivariate analysis was carried out with OPLS-DA to generate an S-Plot. For S-Plot, the cut-offs, ± 0.1 for $p(1)$ and ± 0.7 for $p(\text{corr})[1]$ were used. S-Plot proteins were filtered by FDR-corrected p value to see which were also significant by Benjamin-Hochberg procedure for added statistical stringency. Moreover, we performed receiver operating characteristic (ROC) analysis with MetaboAnalyst 4.0 (metaboanalyst.ca/) to quantify how accurately S-Plot proteins can discriminate between the 2 groups. An AUC value of more than 0.8 is considered good.

Following the identification of significant proteins, enrichment pathway analysis was used to explore the biological pathways of identified proteins of brain-dead donors. Enrichment pathway analysis was performed by Canonical Pathway Analysis in the

web-based bioinformatics application QIAGEN Ingenuity Pathway Analysis (IPA). In this study, a $-\log(p \text{ value})$ of >3 corresponding to a p value of <0.001 was applied for more statistical robustness. In addition, a z -score greater than 1 or smaller than -1 was considered significant.

Then, we performed outcome analysis on recipient freedom from any primary graft dysfunction (PGD) and from severe PGD, recipient freedom from acute rejection with hemodynamic compromise within 30 days after transplantation, and on graft-related 1-year mortality to evaluate the impact of donor plasma protein levels on these clinical endpoints. In outcome analysis on recipient freedom from any primary graft dysfunction (PGD) and from severe PGD, point-biserial correlation analysis was applied on brain-dead donor donors. A correlation coefficient of 0 to 0.4 is considered a weak relationship, a correlation coefficient of 0.4 to 0.7 a moderate relationship, and a correlation coefficient of more than 0.7 is considered a strong relationship.

In outcome analysis on recipient freedom from acute rejection with hemodynamic compromise within 30 days and on graft-related 1-year mortality, univariate Cox regression analysis was performed with brain-dead donor plasma proteins. Next, maximally selected rank statistics algorithms were used to divide donors into high- and low-level subgroups based on different plasma protein levels. Then, the log-rank test was applied to compare recipient rejection and mortality freedom curves between the donor subgroups. Afterward, we generated Kaplan-Meier plots for significant proteins in each subgroup and considered donor proteins with $p < 0.05$ as having a statistically significant effect on recipient rejection and mortality episodes. Finally, multivariate Cox regression was carried out to see the combined predictive effect for significant proteins.

All outcome analyses were performed using survival and survminer packages in R software.

For more details about plasma sample processing, pathway analysis, definitions of clinical outcomes, and statistical analyses, see Methods in Supplementary Materials.

4. RESULTS

Brain-dead donors showed a unique but heterogeneous proteomic profile

The final proteomic analysis consisted of 53 multi-organ donors for HTx, and 23 healthy controls (**Figure 1**). The median age of the organ donors was 44 years, and 10 were female (**Table 1**). We detected 1259 plasma proteins with a minimum of 1 unique peptide by UPLC-MS/MS. For sufficient stringency and confidence in proteomics data, we filtered the proteins with 2 or more unique peptides and obtained 463 quantified proteins. To describe the changes in protein abundance between donors and healthy controls, the fold change was calculated by dividing the mean protein expression of a single protein among donors by the mean expression in controls. The fold change ranged from 0.11 to 2584. For more details on the study population and demographic data, see Results in Supplementary Materials.

Of note is that donor treatment with simvastatin did not classify the treated and untreated donor groups, and therefore was not considered a confounding factor (**Figure S1**).

PCA was performed on all 463 quantified proteins (**Figure 2A**). The scatter plot (t1 versus t2) revealed that samples of donors and healthy controls were only partially separated. Four donors were outside of the 95% confidence ellipse of measurement. The unsupervised learning method of SOM displayed 2 main clusters of protein expression in donors (Donor A and Donor B), 1 of them having 2 subclusters (Donor B1 and Donor B2) (**Figure 2B**, red color for donor samples), and 2 clusters in healthy controls (**Figure 2B**, blue color for healthy control samples), confirming the findings of PCA. A subset of healthy controls and donors merged into the same cluster which was due to the similarity of a few proteins in those samples and the use of the complete set of all 463 quantified proteins in SOM clustering.

To further characterize the separation between donors and healthy controls, supervised multivariate OPLS-DA model and univariate S-Plot were performed. OPLS-DA showed a clear separation between the 2 groups, confirming the findings suggested by PCA and SOM (**Figure 2C**). S-Plot analysis revealed that 32 proteins were statistically significant in both univariate and multivariate analyses between donors and healthy controls, and thereby represent proteins mostly contributing to the differences between donors and healthy controls (**Figure 2D**). Three proteins were upregulated, while 29 proteins were downregulated. Of these proteins, *apolipoprotein A-IV*, *complement C1q C chain*, *leucine-rich alpha-2-glycoprotein 1*, and *14-3-3 protein beta/alpha* showed a good area under the ROC curve (AUC) value of >0.8 (**Table S1**).

Next, we performed univariate analysis to calculate log₂(fold change) and p value using the Wilcoxon-Mann-Whitney test to find out which of 463 proteins were statistically significantly different between donors and healthy controls. Univariate

analysis based on FDR-corrected p value of <0.05 revealed 237 differentially expressed proteins between the donors and healthy controls of which 90 proteins were upregulated, while 147 proteins were downregulated (**Table S2**).

Brain-dead donor protein profile revealed significantly altered pathways

IPA pathway analysis of 237 differentially expressed proteins revealed 65 significant pathways with a p value of <0.05 . Furthermore, using more stringent statistical criteria for protein data set in IPA pathway analysis, we found that 118 proteins with $\log_2(\text{fold change}) \geq 1$ belonged to 58 significant pathways, while 66 proteins with $\log_2(\text{fold change}) \geq 1.5$ showed 50 significant pathways (**Table S3**).

In IPA pathway analysis based on z-score orientation (absolute z-score greater than 1) and the most stringent FDR-corrected p value of <0.001 , we saw that on the one hand coagulation, gluconeogenesis, and glycolysis were significantly enriched, and these pathways showed a trend towards upregulation. On the other hand, complement system, LXR/RXR activation, and production of NO and ROS in macrophages showed a trend toward downregulation (z-score ≤ -1) (**Table 2, Figure S2A-F**). When considering $\log_2(\text{fold change}) \geq 1$, we found that only gluconeogenesis, glycolysis, and xenobiotic metabolism pathways were significant and that they were upregulated. No significant pathway was found with $\log_2(\text{fold change}) \geq 1.5$ (**Table 2**).

Out of 32 S-Plot proteins, 10 S-Plot proteins belonged to the pathways with an absolute z-score greater than 1 and a p value of <0.001 , while the remaining 22 S-Plot proteins were present in other significant pathways. We found that these 10 S-Plot proteins were mostly enriched in coagulation, complement, LXR/RXR activation, and production of NO and ROS in macrophages pathways (**Table 2**).

Proteome profile discriminated 3 subclusters within brain-dead donors

To exclude a methodological artifact of healthy controls to brain-dead donors, we carried out separate statistical analyses including only brain-dead donors and found 3 subclusters within donors with only minor changes in their demographics (**Figure S3, Table 1**). When comparing the recipient outcomes between Donor A and Donor B groups, we could not see any statistically significant difference in PGD, acute rejection, or graft-related survival (**Table 3**). Detailed information, stratified by the Donor subgroups, on the donor demographics and recipient outcomes is given in Tables 1 and 3, and on enriched pathways in Tables S4 and S5, and Supplementary Materials.

Donor plasma *lysine-specific demethylase 3A* was moderately associated with PGD

Next, we investigated whether donor plasma proteins could predict any PGD grade or severe PGD after transplantation. Out of 53 recipients, 17 (32%) recipients developed PGD, and only 6 (11%) had severe PGD. The characteristics of respective donors of recipients with any PGD grade or severe PGD were not statistically different (**Table S6**). However, the recipients with any or severe PGD had longer intubation time, longer stay at ICU and index hospitalization, and higher levels of proBNP, hsTnI, hsTnT, and lactate (**Table S7**).

The point-biserial correlation analysis revealed that only 5 proteins correlated with any PGD, while 6 proteins correlated with severe PGD. Only *lysine-specific demethylase 3A* showed a moderate correlation with any PGD and severe PGD (**Table S8**).

High donor plasma *myosin Va* and *proteasome activator subunit 2* predicted acute rejection episodes with hemodynamic compromise

Next, we investigated whether donor plasma proteins could predict episodes of acute rejections with hemodynamic compromise. Three patients were excluded from the analysis as they expired due to graft-related reasons within 30 days (**Table S9**). Sixteen patients received treatment for acute rejection with hemodynamic compromise. The characteristics of respective donors were not different (**Table S10**). However, the recipients with rejection episodes had significantly higher plasma levels of troponins and lactate during the first 24 hours, higher ProBNP and lower left-ventricle ejection fraction at 1 month, and longer ICU and hospital stay after transplantation (**Table S11**). For more details about specific treatment for acute rejection with hemodynamic compromise, see Results in Supplemental Material.

Univariate Cox regression analysis of differentially expressed 237 proteins revealed that 7 donor plasma proteins were significantly associated with acute rejections with hemodynamic compromise within 30 days. These proteins included *CD163*, *CRP*, *keratin 76*, *myosin Va*, *proteasome subunit alpha type 6*, *proteasome activator subunit 2*, and *transaldolase 1*. We further explored the possibility of an association between acute rejections with hemodynamic compromise and concentration thresholds for these proteins in univariate analysis. After stratification of patients based on each protein expression level, we found that higher donor plasma levels of all these proteins were associated with a significantly increased number of acute rejections with hemodynamic compromise. In Kaplan-Meier analysis, all 7 donor plasma proteins passed the log-rank test with a p value less than 0.05 (**Figure 3A-G, Table 4**). Higher expression of these 7 proteins was linked to higher hazard/risk (**Table 4**).

Additionally, a donor plasma proteomic predictive risk score was calculated based on the concentration levels of these proteins and corresponding regression coefficients. This predictive risk score was calculated by giving 1 point for each of the 7 proteins that were within their respective high-risk levels, therefore yielding a score of 0 to 7 for each donor. In risk score calculation, 18 patients had a score of 0, 16 patients had a score of 1, 6 patients had a score of 2, 5 patients had a score of 3, and 5 patients had a score greater than 3. Based on the donor proteomics risk score, we found that a higher score significantly predicted acute rejection with hemodynamic compromise (Figure 3H). In addition, we observed that donors with a high-risk score (score ≥ 3) had an 80% probability of acute rejection with hemodynamic compromise within 30 days (Figure S4).

In multivariate Cox regression analysis, *myosin Va* and *proteasome activator subunit 2* remained significant suggesting that these 2 proteins are key candidates for prediction of acute rejection with hemodynamic compromise within 30 days after transplantation (Figure S5).

High levels of *moesin* and *lysine-specific demethylase 3A* were associated with worse graft-related 1-year survival

Next, we investigated whether donor proteome could predict graft-related mortality. Out of 53 recipients, 7 recipients died due to graft-related reasons, 6 of them during the first year, and 1 patient died 730 days after transplantation. PGD was the cause of death in 4 patients, acute rejection in 2 patients, and chronic rejection in 1 patient (Table S9). Therefore, we tested whether donor proteome could predict 1-year graft-related mortality.

In univariate analysis, we found that 5 proteins were significantly associated with 1-year graft-related mortality (**Figure 4A-E**). After stratification of donors using maximally selected rank statistics algorithms, we found that high donor plasma levels of *moesin* and *lysine-specific demethylase 3A* were associated with increased graft-related 1-year mortality, while low plasma levels of *D-dopachrome decarboxylase*, *leucine-rich alpha-2-glycoprotein*, and *keratin 79* were associated with decreased graft-related 1-year mortality. In multivariate analysis of 1-year graft-related survival analyses, none of the proteins were significant (**Table 4**).

A summary of the possible biological role of key proteins predicting heart transplant outcome discussed further below, can be found in **Table S12**.

4. DISCUSSION

Heart transplantation using heart allografts from brain-dead organ donors has been established as the gold standard in the treatment of patients with end-stage heart failure. Due to aggravating donor shortage, marginal hearts are increasingly used to improve the availability of donor organs. However, the use of marginal donors with lower organ quality worsens clinical outcomes. Despite remarkable improvements in the management of heart transplants, strategies to optimize the use of scarce donor organs are essential. Novel insights into the molecular pathophysiology of brain-dead organ donors integrated into existing knowledge of involved biological processes may provide liquid biomarker candidates for the detection, prognosis, and treatment of heart transplants with lower quality and increased risk of complication.

Using a label-free proteomics approach, we present the plasma proteomic profile of brain-dead organ donors. We were able to show that brain death induces alterations in protein expression, biological pathways, and pathogenic mechanisms. We found 237 proteins that distinguished brain-dead donors from healthy controls. Based on these 237 identified proteins, 6 significant pathways were enriched, and 32 most significant proteins were filtered by S-Plot, out of which 10 were present in enriched pathways. Enriched pathways were coagulation, complement system, gluconeogenesis, glycolysis, LXR/RXR activation, and production of nitric oxide (NO) and reactive oxygen species (ROS) in macrophages. Moreover, plasma proteins were linked to arteriogenesis and vascular growth, cardiomyocyte and endothelial cell function, and inflammation. Altered biological pathways, mechanisms, and single proteins may play a pivotal role in the pathophysiology of organ injury, acute rejection, primary graft dysfunction (PGD), and mortality. Moreover, single proteins were able to predict heart transplant outcome and thus may be valuable for transplant evaluation

and personalized treatment. If the proteomic profile of an individual donor shows an increased risk of complications after HTx, the care of the donor, transplant, and recipient can be potentially personalized. For example, if a donor proteomic profile indicates a high risk of the development of PGD, enhanced hormonal replacement therapy in donors, faster transport of the transplant, and closer monitoring of cardiac enzymes in recipients may help to decrease the risk of the occurrence of PGD.^{38,39,40}

The crosstalk between complement and coagulation is central to the innate immune response to injury.^{41,42} A key study by Atkinson et al. has demonstrated that brain death triggers complement activation and ischemia-reperfusion injury in heart transplants. Moreover, Atkinson et al. recognized that recipients of brain-dead donor grafts have a higher risk of acute rejection and graft failure than recipients of living donor grafts. This may be due to more complement activation and cardiac injury, suggesting that a complement inhibition treatment in recipients may alleviate cardiac injury and result in better clinical outcomes.⁴³ In our study, brain death was linked to an overall upregulation of coagulation and a downregulation of the complement system whilst S-Plot proteins being present in pathways were downregulated in donors. In donor subgroup analyses, the Donor B subgroup with more hypertension and traumatic brain injury as well as the Donor B1 subgroup with higher CRP and troponin within 24h and reduced heart function 7 days after HTx showed an upregulation of complement pathway. Nevertheless, our findings indicate that the shortage of anticoagulant proteins *antithrombin-III*, *plasminogen* and *protein C* may aggravate microvascular thrombosis, and reduce optimal myocardial reperfusion in the heart recipient. In a study performed by Labarrere et al., endomyocardial biopsies were taken from 141 heart transplant recipients 3 months after HTx, and the presence of vascular *antithrombin* was assessed by immunohistochemistry. Interestingly, heart transplants with a lack of

vascular *antithrombin* had an increased risk of cardiac allograft vasculopathy and heart transplant failure, while transplants with recovered vascular *antithrombin* showed better clinical outcome after HTx.⁴⁴

Excessive coagulation, inappropriate innate immune response, and ischemia-reperfusion injury may have led to the depletion of the LXR/RXR pathway in brain-dead donors. Prior studies have noted the importance of LXR/RXR as lipid-sensing transcription factors that link lipid metabolism with protective immune response and attenuation of ischemia-reperfusion injury.^{45,46} One study by Xu et al. has assessed the impact of *apolipoprotein A4* on thrombosis in human plasma samples and reported that *apolipoprotein A4* inhibited thrombocyte aggregation and thrombus formation.⁴⁷ In our study, we observed decreased *apolipoprotein A4* levels which may worsen thrombosis after brain death. A considerable amount of literature has been published on the kinin-kallikrein system which contributes to coagulation, vascular inflammation, and vasodilatation. *Kininogen-1* plays a key role as it mediates the assembly of the kinin-kallikrein system.^{48,49} Griangreco et al have analyzed 88 pre-transplant samples and found that a decreased plasma level of *kallikrein* was a robust predictor of PGD, particularly in combination with pre-transplant ionotropic treatment.⁵⁰ The impact of *paraoxonase-1* on endothelium was studied by García-Heredia et al. They reported that *paraoxonase-1* has anti-apoptotic and anti-oxidative effects on endothelial cells.⁵¹ We found that levels of *paraoxonase-1* were lower in brain-dead donors compared to controls. Taken together, the low levels of *paraoxonase-1* may make heart transplants more susceptible to endothelial cell damage by oxidation and apoptosis.

On one hand, myocardial injury may be aggravated by increasing decoupling of glycolysis and glucose oxidation as reported by Opie et al. and Lee et al..^{52,53} In our

brain-dead donors, glycolysis may be upregulated for anaerobic ATP production, while normal cardiac ATP production from fatty acid oxidation may be downregulated.⁵⁴ Several studies have shown that upregulation of gluconeogenesis may worsen hyperglycemia and systemic inflammation in brain-dead donors.^{55,56,57} In a study conducted by Aljiffry et al., 15 human brain-dead organ donors were divided into one group which was treated with high-dose insulin, and one control group without insulin treatment. The insulin-treatment group showed preserved normoglycemia and suppressed systemic inflammation, providing support for the hypothesis that insulin treatment of brain-dead donors may mitigate transplant injury and improve clinical outcome.⁵⁸

On the other hand, oxidative myocardial stress may be worsened by the observed downregulation of the production of NO and ROS in macrophages pathway which may lead to less NO bioavailability. Because generation of NO activates *aldose reductase*, less NO availability may weaken the *aldose reductase* activity which metabolizes lipid peroxidation products and protects the heart against oxidative injury. To investigate the cardioprotective properties of *aldose reductase*, Kaiserova et al. have treated the hearts of rats with NO synthase inhibitors before initiating ischemia. After reperfusion, the absence of *aldose reductase* activation was seen which resulted in the intensification of ischemia-reperfusion injury.⁵⁹

After protein set enrichment analysis, we used uni- and multivariate analyses to investigate if donor plasma proteins may predict heart transplant outcomes such as any or severe PGD, acute rejection with hemodynamic compromise, and graft-related 1-year mortality. Interestingly, we found a couple of proteins that were in addition to any or severe PGD associated with multiple clinical endpoints. *Keratin 76* was

associated with severe PGD and acute rejection with hemodynamic compromise, *Lysine-specific demethylase 3A* with any and severe PGD, and 1- survival, *moesin* with severe PGD and 1-year survival, and *proteasome 20s subunit alpha 6* with severe PGD and acute rejection with hemodynamic compromise.

In univariate analysis of acute rejection with hemodynamic compromise, higher donor plasma levels of *CD163*, *CRP*, *keratin 76*, *myosin Va*, *proteasome subunit alpha type-6*, *proteasome activator subunit 2*, and *transaldolase 1* were correlated with acute rejection during the first month after HTx. In multivariate analysis of acute rejection with hemodynamic compromise, we found *myosin Va* and *proteasome activator subunit 2* as the best predictors for the development of acute rejection episodes.

The study by Schumacher-Bass et al. (2014) offers probably the most comprehensive analysis of the intracellular motor protein *myosin Va* which takes part in cardiac ion channel trafficking. They found that *myosin Va* mediates the cell surface trafficking of the human voltage-gated potassium channel Kv1.5 in cardiac myocytes. Activation of Kv1.5 generates the cardiac ultra-rapid delayed rectifier potassium current (IKur) which is a major repolarizing current in human atrial myocytes. Due to their central role in atrial action potential, *myosin Va* and Kv1.5 have been suggested as promising therapeutical targets to maintain atrial rhythm and treat atrial fibrillation.^{60,61} Over the past years, research has highlighted that atrial fibrillation after HTx is an important determinant of clinical outcome. Early posttransplant atrial fibrillation was shown to be associated with acute rejection and increased mortality, especially in recipients receiving heart transplants from donors with older age.^{62,63,64,65} In 2021, Darche et al. included 639 heart recipients in a study at Heidelberg Heart Center to analyze the association between atrial fibrillation before HTx and 1-month after HTx. They found

that atrial fibrillation before HTx is a central risk factor for posttransplant atrial fibrillation, permanent pacemaker implantation, and mortality after HTx.⁶⁶ We hypothesize that heart transplants from donors with elevated *myosin Va* levels may be more prone to pre- and posttransplant atrial fibrillation and ultimately to acute rejection. However, in our study we have not collected the data about the occurrence of atrial fibrillation. If our hypothesis can be proven by future studies, we suggest that heart transplants with high *myosin Va* levels may be possibly treated with either established antiarrhythmic drugs such as amiodarone or so far non-established drugs such as peptide inhibitors to minimize the risk of development of atrial fibrillation.^{67,68}

Proteasome activator subunit 2 is a proteasome activator (PA28) subunit that activates the circulating 20s proteasome. Faries et al. took vascular biopsies from 70 patients to study the effects of proteasome activation on the human vascular system. They have been able to show that abnormal proteasome activation enhances intimal hyperplasia which represents the early stage of atherosclerosis.⁶⁹ When comparing intimal hyperplasia and atherosclerosis in non-transplant patients with acute graft rejection and cardiac vascular vasculopathy in transplant patients, it appears that their pathophysiology is based on initial endothelial response to injury. In HTx, alloimmune-responses cause a severely injured and dysfunctional endothelium which is a key contributor to acute and long-term graft failure. The injury of microvascular endothelial cells causes permeability dysfunction, hemorrhage, and thrombosis which precede ischemic graft damage, acute rejection, or fibrosis. The injury of macrovascular endothelial cells alters endothelial permeability which stimulates vascular smooth muscle cell-mediated intimal hyperplasia and vasodilatory dysfunction.⁷⁰ Intimal hyperplasia can be seen as a precursor of cardiac allograft vasculopathy, a particular

type of coronary atherosclerosis that represents the most common cause of late graft failure.⁷¹

Next, we investigated if the individual risk of brain-dead donors for acute rejection with hemodynamic compromise can be detected by a donor plasma proteomic immunological risk score. Our results showed that the individual risk increases depending on how many of the 7 proteins were increasingly expressed. On this basis, we conclude that the risk score may be used for pre-transplant risk assessment and management of the therapy regimen.

In univariate Cox regression analysis of graft-related 1-year mortality, higher donor plasma levels of *lysine-specific demethylase 3A* and *moesin* were related to a higher risk of mortality. An animal study by Zhang et al. investigated the central regulators of pathological myocardial fibrosis. It was shown that *lysine-specific demethylase 3A* controls myocardial fibrosis, and thus it has been discussed as a novel pharmacological target to treat fibrosis and cardiac hypertrophy.⁷² *Moesin* is primarily expressed in vascular endothelial cells and promotes endothelial hyperpermeability and vascular inflammation. In the question of the clinical utility of *moesin* as a biomarker, Chen et al. found that increased *moesin* levels were associated with microvascular injury in septic patients and suggested *moesin* as a novel biomarker for the evaluation of sepsis severity.⁷³ Yamani et al. examined the progression of coronary vasculopathy in 140 heart transplant patients within 1-year after HTx by intravascular ultrasound. They found that pretransplant myocardial ischemia injury triggers early fibrosis and that early fibrosis is associated with the early development of coronary allograft vasculopathy after HTx.⁷⁴ Together, our findings lead to a similar conclusion where high expression of *lysine-specific demethylase 3A* and *moesin* in brain-dead

organ donors may be closely linked to the occurrence of microvascular injury, myocardial fibrosis, and cardiac allograft vasculopathy by which they may indicate a worse transplant quality.

Our data show that single donor plasma proteins, enriched biological pathways as well as pathogenic mechanisms play a pivotal role in the pathophysiology of brain death-induced heart transplant injury which affects the risk of later transplant complications. We filtered a panel of donor plasma proteins which may be promising liquid biomarker candidates to assess the risk of individual heart transplants. In future clinical practice, minimally invasive peripheral plasma samples could be taken from organ donors immediately after declaration of brain death. The proteomics-derived biomarker profile could be analyzed in vitro by LC-MS/MS for real-time assessment of heart transplant's individual risk of acute rejection with hemodynamic compromise, PGD, and mortality. Once the individual heart transplant risk is assessed, medical treatment could be adjusted during donor management, organ retrieval, organ preservation, heart transplantation, and post-transplant follow-up. For example, if a brain-dead organ donor shows a suspicious protein biomarker profile predicting a high risk of development of PGD, enhanced hormonal replacement therapy with thyroid hormones and high-dose steroids could be administered to the donor to protect against PGD.^{75,76,77} Furthermore, insulin could be given to maintain normoglycemia and reduce the inflammatory response in brain-dead organ donors.^{78,79} After retrieval of the donor organ, the fastest possible transport, in case of long travel distances with an ambulance jet or helicopter, should be chosen to minimize the ischemic time.⁸⁰ During heart transplantation, the cardiopulmonary bypass time should be as short as possible to mitigate PGD-associated ischemic injury.⁸¹ In addition to the use of protein biomarker signatures in brain-dead donor assessment, cardiac troponin

measurements in recipients could be used to monitor the remaining risk of the development of PGD. In our study, heart recipients with any and severe PGD showed significantly higher hsTnI and hsTnT levels at 6, 12, and 24 hours after transplantation. Our observation is supported by a recently published study on the potential role of elevated troponin levels in the risk of the development of PGD.⁸²

As shown in this discovery study, LC-MS/MS can be used to find plasma protein panels that may be successfully implemented in future clinical practice. LC-MS is becoming increasingly popular in clinical practice, having previously been used primarily in clinical research. Today LC-MS/MS is already an established tool in clinical practice for in vitro diagnostics. Dried blood spots are analyzed for therapeutic drug monitoring during the treatment with immunosuppressive drugs after solid organ transplantation or newborns are screened for metabolic disorders.^{83,84} However, the LC-MS/MS analysis workflow of a whole blood sample still requires numerous manual steps, and thus more technical advances are needed to run the LC-MS/MS in an increasingly fully automated and faster manner.⁸⁵

Despite its relatively small sample size and single-center approach, we consider this study meaningful. The size of the brain-dead organ group is naturally small due to the overall rather small number of HTx performed in Finland. However, all HTx in Finland are performed at the Helsinki University Hospital and therefore our sample size covers Finland representatively.

In conclusion, we present the plasma proteome signature of brain-dead organ donors using an open-label proteomic approach. We show that brain death alters plasma protein expression and characterize these changes in a systems biology approach.

Our results elucidate the complex unphysiological state of brain-dead organ donors and highlight key proteins that may play a vital role in altered biological mechanisms and pathways of brain-dead organ donors. Several of those proteins and biological processes are associated with the clinical outcome after HTx. Our results cast a new light on the potential of donor plasma proteome in biomarker discovery research. Further research on the effects of the proteins, the potential of novel treatment targets, and the utility of proposed biomarker candidates in acute rejection with hemodynamic compromise, PGD, and 1-year mortality is needed.

While this study successfully elucidates the proteomic signature of brain-dead heart organ donors in Finland, the plasma proteome of our heart donors may partly differ from the heart donor proteome in other world regions for two reasons. Firstly, our heart donor group consists of “high-quality” donors as donors with high age, low ejection fraction, severe left ventricular hypertrophy, and high-dose inotropic treatment were excluded from the study. Therefore, our preselected donor group may not include those donors who are increasingly considered and used as suboptimal donors in other transplantation cohorts.⁸⁶ Secondly, our donor group is characterized by the genetic homogeneity of the Finnish population. Therefore, we suggest international multi-center studies with more heterogeneous donor cohorts to compare the results of a Finnish cohort with HTx cohorts in other countries. Furthermore, further studies with larger sample sizes are necessary to validate and test suggested biomarker candidates before aiming for a successful clinical implementation in the future.

Nevertheless, our results suggest that plasma proteome analysis may improve the outcome of HTx.

6. APPENDIX

6.1 FIGURES

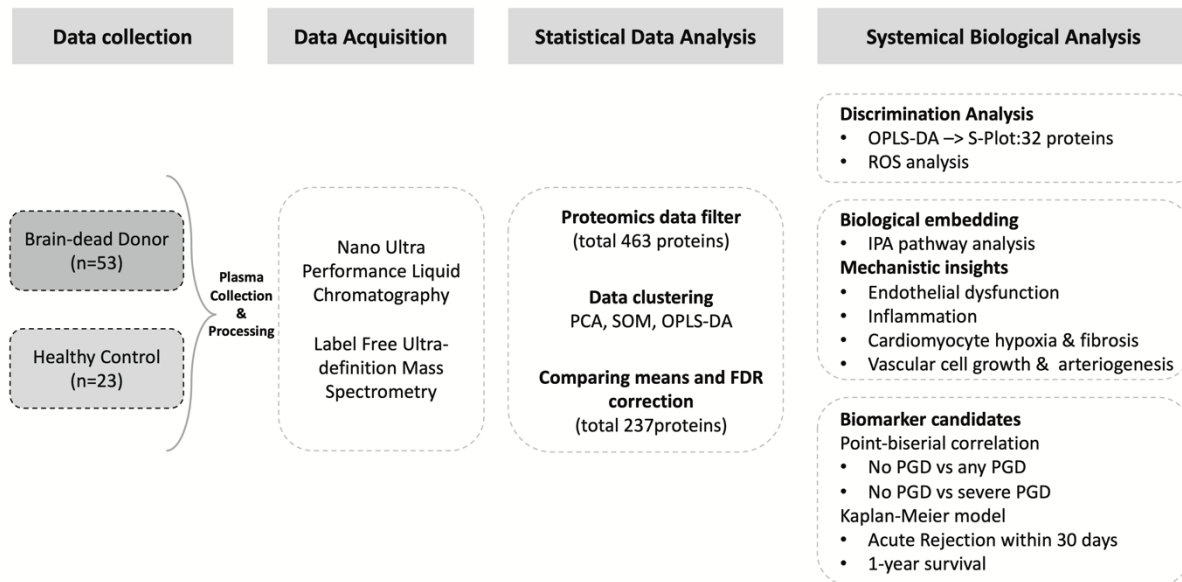

Figure 1. Flow chart of the study

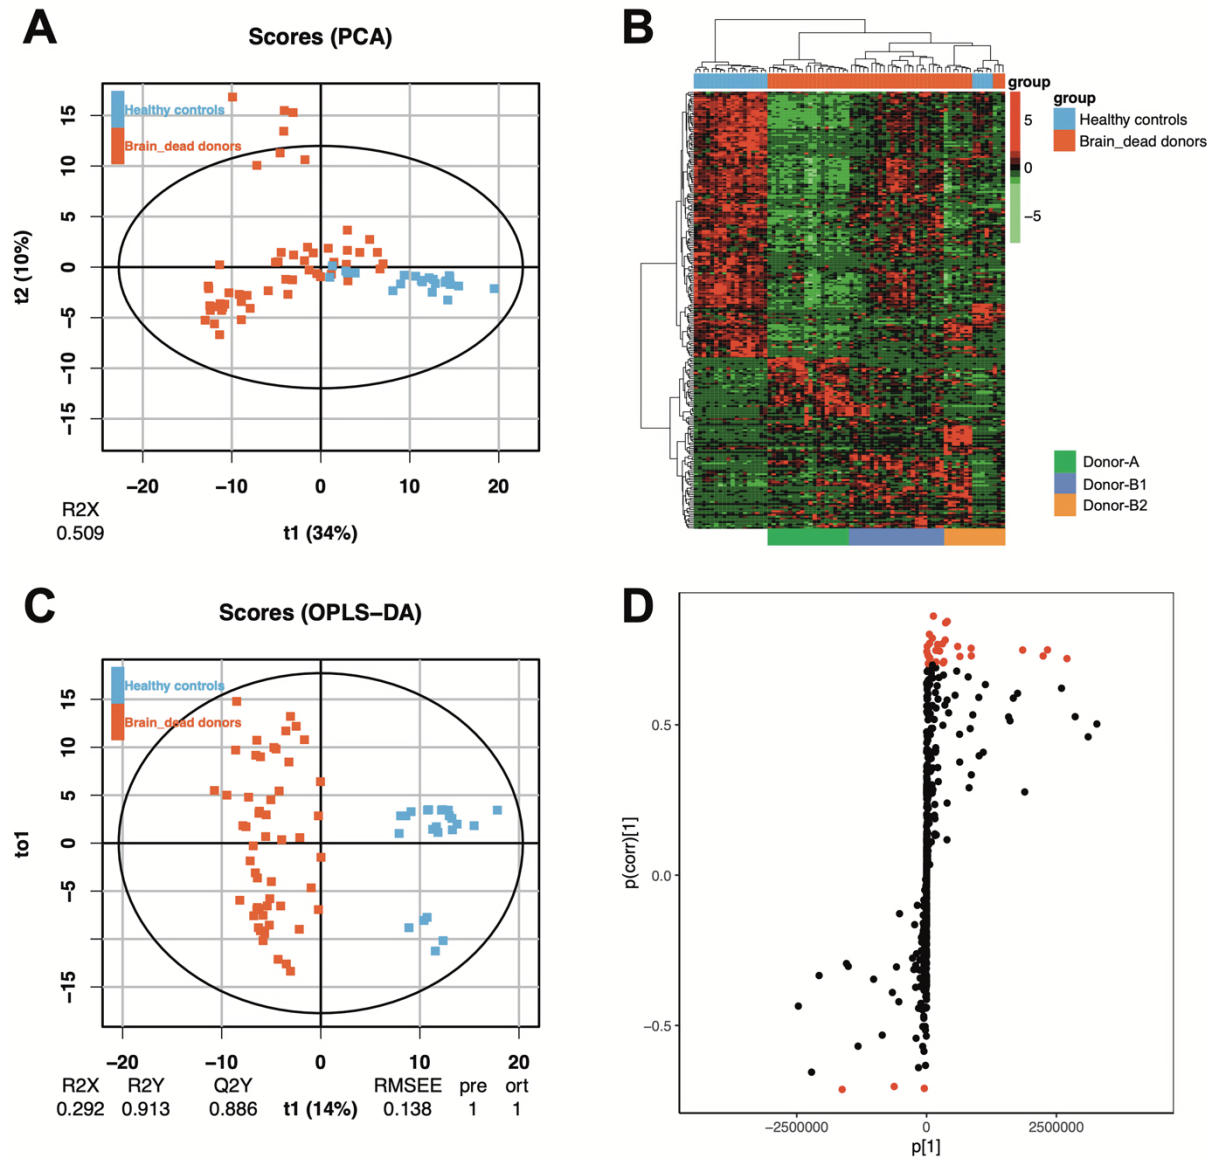

Figure 2. Comparison of differentially expressed plasma proteins between brain-dead donors and healthy controls.

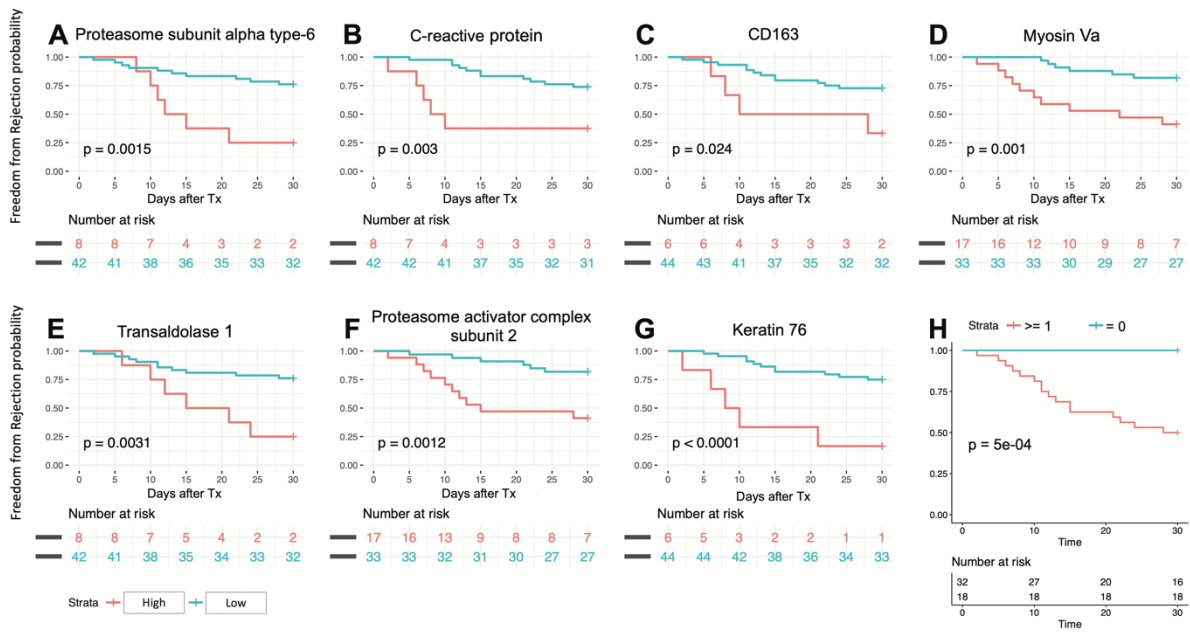

Figure 3. Impact of donor plasma protein levels on the development of acute rejection with hemodynamic compromise within the first 30 days after heart transplantation.

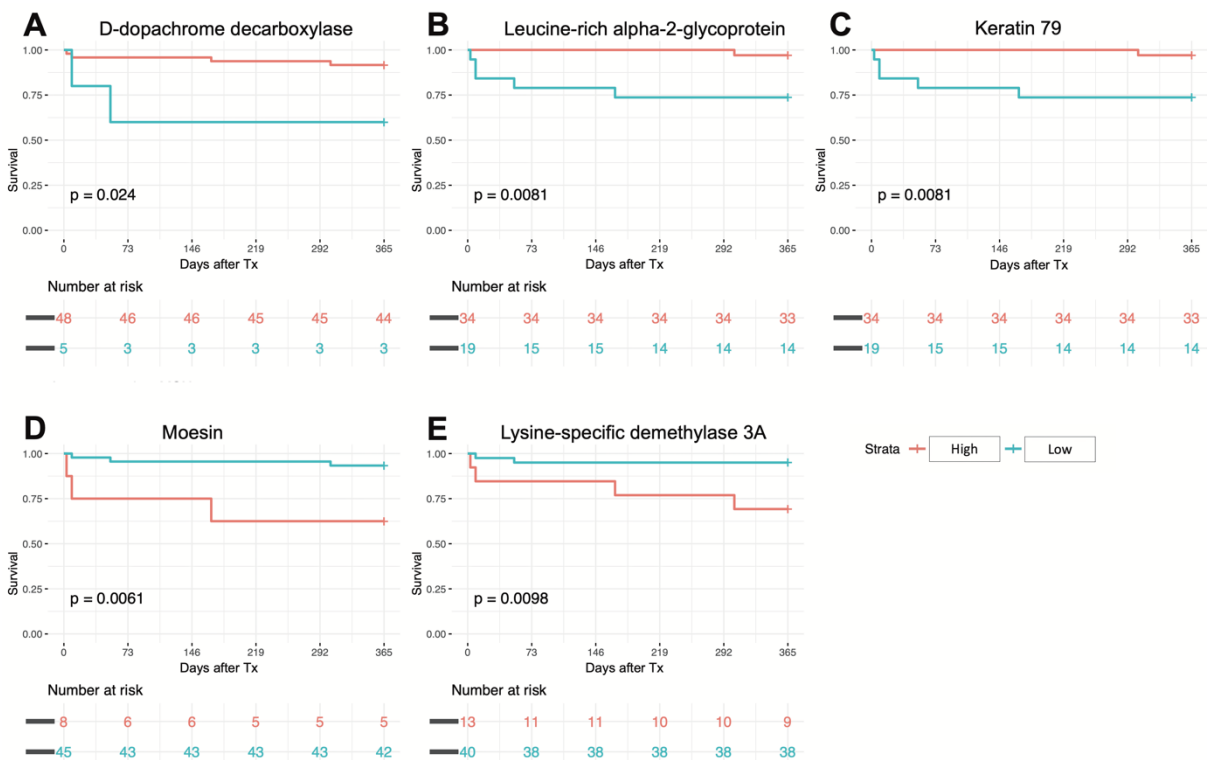

Figure 4. Impact of donor plasma protein levels on graft-related 1-year survival after heart transplantation.

6.2 TABLES

Table 1. Clinical characteristics of brain-dead heart transplant donors and allocation of other solid organs based on different donor plasma proteome profiles.

Donor characteristics	All donors (N=53)	Donor A (N=20)	Donor B (N=33)	Donor B1 (N=26)	Donor B2 (N=7)

Plus-minus values are mean \pm SD; values with range in parentheses are median (interquartile range). P values are *P<0.05. **P<0.01. ***P<0.001. During the first 24 hours, there was no difference in CKMB, lactate, and leukocytes between the donor groups. In addition, there was no difference in the function of heart transplants measured by ProBNP, and LV-EF between the donor groups after 7 days. †In the previous medical history of the heart transplant recipients, there was no peripheral vascular disease. *Acute rejection with hemodynamic compromise was diagnosed based on clinical decisions such as a clinically significant decrease in left-ventricular function, an increase in left-ventricular wall thickness, and/or arrhythmias. The diagnosis of acute rejection with hemodynamic compromise always required that the patient was treated with a high dose of intravenous pulse steroids and/or antithymocyte globulin. *Acute rejection with myocyte damage is equal to or more than G1Rb rejection. In this study cohort, we did not see any cases of antibody-mediated rejection within 30-days or 1-year after HTx.

BACKGROUND: The pathophysiological changes related to brain death may affect the quality of the transplanted organs and expose the recipients to risks. We probed systemic changes reflected in donor plasma proteome and investigated their relationship to heart transplant outcomes.

METHODS: Plasma samples from brain-dead multi-organ donors were analyzed by label-free protein quantification using high-definition mass spectrometry. Unsupervised and supervised statistical models were used to determine proteome differences between brain-dead donors and healthy controls. Proteome variation and the corresponding biological pathways were analyzed and correlated with transplant outcomes.

RESULTS: Statistical models revealed that donors had a unique but heterogeneous plasma proteome with 237 of 463 proteins being changed compared to controls. Pathway analysis showed that coagulation, gluconeogenesis, and glycolysis pathways were upregulated in donors, while complement, LXR/RXR activation, and production of nitric oxide and reactive oxygen species in macrophages pathways were downregulated. In point-biserial correlation analysis, lysine-specific demethylase 3A was moderately correlated with any grade and severe PGD. In univariate and multivariate Cox regression analyses myosin Va and proteasome activator complex subunit 2 were significantly associated with the development of acute rejections with hemodynamic compromise within 30 days. Finally, we found that elevated levels of lysine-specific demethylase 3A and moesin were identified as predictors for graft-related 1-year mortality in univariate analysis.

CONCLUSIONS: We show that brain death significantly changed plasma proteome signature. Donor plasma protein changes related to endothelial cell and cardiomyocyte function, inflammation, and vascular growth and arteriogenesis could predict transplant outcome suggesting a role in donor evaluation. *J Heart Lung Transplant* 2022;41:311–324

Brain death is the result of irreversible injury of the central nervous system. The injury may lead to systemic inflammatory, hormonal, and metabolic changes, as well as affect peripheral organs and compromise cardiorespiratory function. This may increase the risk of primary graft dysfunction, acute rejection, and survival of the recipient.^{1–4}

Most of our understanding of donor organ quality is based on studies investigating donor demographics, clinical parameters, and a limited number of cytokines or proteins.^{5,6} In the last few years, high-throughput technologies have advanced the discovery of pathophysiological molecular signatures. The ultra-high-performance liquid chromatography, connected to tandem mass spectrometry (UPLC-MS/MS), has facilitated a detailed measurement of the plasma proteome. In systemic biology approach, uni- and multivariate statistical analyses identify proteins that distinguish a group from another. This allows the integration of proteomics data with existing knowledge of involved biological processes and detailed examination of potential.⁷

Our results show that brain death induced prominent protein expression and pathway alterations in the donor plasma proteome. Furthermore, changes in donor plasma protein related to endothelial cell and cardiomyocyte function, inflammation, and vascular growth and arteriogenesis could predict transplant outcome suggesting their role in donor evaluation. To conclude, our results enhance the understanding of the plasma proteome in brain-dead donors, and changes in their signature may be used to predict the heart transplant outcome.

Methods

Study design and study population

This study is a post hoc analysis of multi-organ donors participating in a prospective, randomized clinical trial on the effects of donor simvastatin treatment on ischemia-reperfusion injury after heart transplantation (Nykänen et al.).⁸ We analyzed donor plasma protein samples by nano ultra-performance liquid chromatography and quantified them with UPLC-MS/MS and investigated their relationship to heart transplant outcome. Plasma samples were collected in lithium heparin tubes before heparinization and organ procurement. After cooling down, we used the “Top 12 Abundant Protein Depletion kit” (Pierce, Thermo Fisher) to deplete greater than 95% of the most abundant proteins from 10 μ l of plasma. The list of 12 depleted proteins was alpha-1-lacid-glycoprotein, alpha-1-antitrypsin, alpha-2-macroglobulin, albumin, apolipoprotein A-I, apolipoprotein A-II, fibrinogen, haptoglobin, IgA, IgG, IgM, and transferrin and the remaining proteins were digested by trypsin. UPLC-MS/MS was performed as described.⁹ Out of the original 84 trial donors and recipients, 54 donors were chosen for proteomics analysis as they had complete sets of all time points samples available of the donor and recipient pair. Label-free quantification failed on 1 donor sample due to batch effect, therefore this sample was excluded from the study. Control samples were collected from 24 healthy controls. One

control sample failed normalization and was removed from the study. For details about donor inclusion and exclusion criteria, donor management, plasma sample processing, definitions of clinical outcomes, and bioinformatics and statistical analyses, see Methods in Supplemental Material.

Results

Brain-dead donors showed a unique but heterogeneous proteomic profile

The final proteomic analysis consisted of 53 multi-organ donors for HTx, and 23 healthy controls (Figure 1). The median age of the organ donors was 44 years, and 10 were female (Table 1). We detected 1259 plasma proteins with a minimum of 1 unique peptide by UPLC-MS/MS. For sufficient stringency and confidence in proteomics data, we filtered to the proteins with 2 or more unique peptides and obtained 463 quantified proteins. To describe the changes in protein abundance between donors and healthy controls, the fold change was calculated by dividing the mean protein expression of a single protein in donors by mean expression in controls. The fold change ranged from 0.11 to 2584.

Of note is that donor treatment with simvastatin did not classify the treated and untreated donor groups, and therefore was not considered a confounding factor (Figure S1).

PCA was performed on all 463 quantified proteins (Figure 2A). The scatter plot (t1 versus t2) revealed that samples of donors and healthy controls were only partially separated. Four donors were outside of the 95% confidence ellipse of measurement. The unsupervised learning method of SOM displayed 2 main clusters of protein expression in donors (Donor A and Donor B), 1 of them having 2 subclusters (Donor B1 and Donor B2) (Figure 2B, red color for donor samples), and 2 clusters in healthy controls (Figure 2B, blue color for healthy control samples), confirming the findings of PCA. A subset of healthy controls and donors merged into the same cluster which was due to the similarity of few proteins in those samples and the use of the complete set of all 463 quantified proteins in SOM clustering.

To further characterize the separation between donors and healthy controls, supervised multivariate OPLS-DA model and univariate S-Plot were performed. OPLS-DA showed a clear separation between the 2 groups, confirming the findings suggested by PCA and SOM (Figure 2C). S-Plot analysis revealed that 32 proteins were statistically significant in both univariate and multivariate analyses between donors and healthy controls, and thereby represent proteins mostly contributing to the differences between donors and healthy controls (Figure 2D). Three proteins were upregulated, while 29 proteins were downregulated. Of these proteins, apolipoprotein A-IV, complement C1q C chain, leucine-rich alpha-2-glycoprotein 1, and 14-3-3

Figure 1 Flow chart of the study.

Data collection. One control sample failed normalization and was removed. One donor sample failed due to batch effect and was removed. Data acquisition. Label-free ultra-definition mass spectrometry presents the structural identity of the individual peptides based on the mass to charge ratio. Nano ultra performance liquid chromatography as the second part of this tandem method (UPLC-MS) separates peptides within the plasma sample. Statistical Data Analysis. 463 proteins were quantified which contained 2 or more unique peptides. Principal component analysis (PCA) was used as a clustering technique to determine if the protein expression separates organ donors and healthy controls as two classes and to find the expressed proteins that explain the majority of the variance noticed in a much bigger number of measured protein expressions. Self-organizing map (SOM) was used to visualize and analyze high-dimensional proteomics datasets by presenting them as lower-dimensional ones. Orthogonal projections to latent structure-discriminant analysis (OPLS-DA) is a regression model method to discriminate 2 or more classes using multivariate proteomics data. Benjamini-Hochberg FDR correction revealed 237 identified proteins with FDR-corrected p value <0.05 , accounting for differences between the classes which are visualized in PCA, SOM, and OPLS-DA. Systemical Biological Analysis. S-Plot was created based on OPLS-DA loadings plot to extract 32 statistically most significant proteins between brain-dead donors and healthy controls. IPA pathway enrichment analysis was performed on 237 identified proteins. Point-biserial correlation analysis was applied to investigate the correlation between donor plasma proteome and any PGD or severe PGD. Kaplan-Meier model was applied on the clinical outcome endpoints 30 days rejection with hemodynamic compromise and 1-year survival to find biomarker candidates among 237 identified proteins in brain-dead donors.

protein beta/alpha showed a good area under the ROC curve (AUC) value of >0.8 (Table S1).

Next, we performed univariate analysis to calculate \log_2 (fold change) and p value using the Wilcoxon-Mann-Whitney test to find out which of 463 proteins were statistically significantly different between donors and healthy controls. Univariate analysis based on FDR-corrected p value of <0.05 revealed 237 differently expressed proteins between the donors and healthy controls of which 90 proteins were upregulated, while 147 proteins were downregulated (Table S2).

Brain-dead donor protein profile revealed significantly altered pathways

IPA pathway analysis of 237 differentially expressed proteins revealed 65 significant pathways with a p value of <0.05 . Furthermore, using more stringent statistical criteria for protein data set in IPA pathway analysis, we found that 118 proteins with $\log_2(\text{fold change}) \geq 1$ belonged to 58 significant pathways, while 66 proteins with $\log_2(\text{fold change}) \geq 1.5$ showed 50 significant pathways (Table S3).

In IPA pathway analysis based on z -score orientation (absolute z -score greater than 1) and the most stringent FDR-

corrected p value of <0.001 , we observed that on the one hand coagulation, gluconeogenesis, and glycolysis were significantly enriched, and these pathways showed a trend towards upregulation. On the other hand, complement system, LXR/RXR activation, and production of NO and ROS in macrophages showed a trend towards downregulation (z -score ≤ -1) (Table 2, Figure S2A-F). When considering \log_2 (fold change) ≥ 1 , we found that only gluconeogenesis, glycolysis, and xenobiotic metabolism pathways were significant and that they were upregulated. No significant pathway was found with $\log_2(\text{fold change}) \geq 1.5$ (Table 2).

Out of 32 S-Plot proteins, 10 S-Plot proteins belonged to the pathways with absolute z -score greater than 1 and p value of <0.001 , while the remaining 22 S-Plot proteins were present in other significant pathways. We found that these 10 S-Plot proteins were mostly enriched in coagulation, complement, LXR/RXR activation, and production of NO and ROS in macrophages pathways (Table 2).

Proteome profile discriminated 3 subclusters within brain-dead donors

To exclude a methodological artifact of healthy controls to brain-dead donors, we carried out separate statistical

Plus-minus values are mean ±SD; values with the range in parentheses are median (interquartile range). P values are marked as asterisks (**p*<0.05. ***p*<0.01. ****p*<0.001). CMV, indicates cytomegalovirus; HDL, high-density lipoprotein; LDL, low-density lipoprotein; ROSC, return of spontaneous circulation; and Tx, transplantation.

^aIn the previous medical history of the donors there was no coronary artery disease, chronic obstructive pulmonary disease, peripheral vascular disease, previous malignancy, prior stroke, and no history of sternotomy.

^bDonor coronary angiography was performed for donors with >40 years of age, strong family history of coronary disease, or smoking.

analyses including only brain-dead donors and found 3 sub-clusters within donors with only minor changes in their demographics (Figure S3, Table 1). When comparing the recipient outcomes between Donor A and Donor B groups, we could not see any statistically significant difference in

PGD, acute rejection, or graft-related survival (Table 3). Detailed information, stratified by the Donor subgroups, on the donor demographics and recipient outcomes is given in Tables 1 and 3, and on enriched pathways in Tables S4 and S5, and Supplement.

Figure 2 Comparison of differentially expressed plasma proteins between brain-dead donors and healthy controls.

Unsupervised PCA analysis was performed on 463 quantified proteins. In PCA analysis, the t1 axis showed the variation of plasma proteins between the brain-dead donors (orange dots) and healthy controls (blue dots), whereas the t2 axis showed the variation of protein profile within the same group. The 95% confidence ellipse showed that 4 out of 53 heart donors had increased protein expression heterogeneity. Within 95% confidence ellipse, brain-dead donor samples, as well as healthy control samples, were grouped into two major clusters. (B) SOM clustering of all 463 quantified plasma proteins in the heatmap showed separate clusters in brain-dead donors (orange) and healthy controls (blue), confirming the observation of the PCA plot. Red color represents upregulated, and green color downregulated protein expression in samples. Donor samples grouped into Donor A (dark green), Donor B1 (pink), and Donor B2 (orange). Subsets of healthy controls (blue, right side) and Donor B2 (orange, right side) grouped into the same cluster. (C) Supervised OPLS-DA analysis on 463 quantified plasma proteins showed a clear separation between the 2 groups, confirming the findings suggested by PCA and SOM. (D) S-Plot generated from the OPLS-DA analysis revealed 32 significant differentially expressed proteins between brain dead donors and healthy controls. The right upper corner of the Figure shows that 29 proteins were downregulated, whereas the left lower corner shows that 3 proteins were upregulated in brain dead donors. Proteins with the cut-offs, ± 0.1 for $p[1]$ and $> +0.7$ or < -0.7 for $p(\text{corr})[1]$ were considered as significant proteins. (Color version of figure is available online)

Donor plasma lysine-specific demethylase 3A was moderately associated with PGD

Next, we investigated whether donor plasma proteins could predict and any PGD grade or severe PGD after transplantation. 17 of 53 recipients (32%) recipients developed PGD and only 6 (11%) had severe PGD. The characteristics of respective donors of recipients with any PGD grade or severe PGD were not statistically different (Table S6). However, the recipients with any or severe PGD had longer intubation time, longer stay at ICU and index hospitalization, and higher levels of proBNP, hsTnI, hsTnT, and lactate (Table S7).

The point-biserial correlation analysis revealed that only 5 proteins correlated with any PGD, while 6 proteins

correlated with severe PGD. Only lysine-specific demethylase 3A showed a moderate correlation with any PGD and severe PGD (Table S8).

High donor plasma myosin Va and proteasome activator subunit 2 predicted acute rejection episodes with hemodynamic compromise

Next, we investigated whether donor plasma proteins could predict episodes of acute rejections with hemodynamic compromise. The prerequisite to establish the diagnosis of acute rejection with hemodynamic compromise was that the patient was treated by high dose of intravenous pulse steroids and/or anti-thymocyte globulin. Three patients

were excluded from the analysis as they expired due to graft-related reasons within 30 days (Table S9). Sixteen patients received treatment for acute rejection with hemodynamic compromise. The characteristics of respective donors were not different (Table S10). However, the recipients with rejection episodes had significantly higher plasma levels of troponins and lactate during the first 24 hours, higher ProBNP and lower left-ventricle ejection fraction at 1 month, and longer ICU and hospital stay after transplantation (Table S11).

Univariate Cox regression analysis of differentially expressed 237 proteins revealed that 7 donor plasma proteins were significantly associated with acute rejections with hemodynamic compromise within 30 days. These

proteins included CD163, CRP, keratin 76, myosin Va, proteasome subunit alpha type 6, proteasome activator subunit 2, and transaldolase 1. We further explored the possibility of an association between hemodynamically compromised acute rejection rejections and concentration thresholds for these proteins in univariate analysis. After stratification of patients based on each protein expression level, we found that higher donor plasma levels of all these proteins were associated with a significantly increased number of acute rejections with hemodynamic compromise. In Kaplan-Meier analysis, all the 7 donor plasma proteins passed the log-rank test with a *p* value less than 0.05 (Figure 3A-G, Table 4). Higher expression of these 7 proteins was linked to higher hazard/risk (Table 4).

Table 2 Effect of log2 Fold Change on Ingenuity Pathway Analysis of Identified Proteins in Heart Transplant Donors

Pathway (z-score =>1)	Donor vs Controls	-log(p value)	Donor vs Controls	-log(p value)	Donor vs Controls	-log(p value)	Donor A vs. B	Donor B1 vs B2	S-Plot proteins

In IPA pathway analysis, we considered pathways with a $-\log(p \text{ value})$ of >3.0 ($p \text{ value} < 0.001$) and a z-score of ± 1 as significant. Upregulated pathways are highlighted in red and downregulated in green. S-Plot proteins enriched into specific pathways are presented.

Additionally, a donor plasma proteomic predictive risk score was calculated based on the concentration levels of these proteins and corresponding regression coefficients. This predictive risk score was calculated by giving 1 point for each of the 7 proteins that were within their respective high-risk levels, therefore yielding a score of 0 to 7 for each donor. In risk score calculation, 18 patients had a score of 0, 16 patients a score of 1, 6 patients a score of 2, 5 patients a score of 3, and 5 patients had a score greater than 3. Based on the donor proteomics risk score, we found that a higher score significantly predicted acute rejection with hemodynamic compromise (Figure 3H). In addition, we observed that donors with high-risk score (score ≥ 3) had an 80% probability of acute rejection with hemodynamic compromise within 30 days (Figure S4).

In multivariate Cox regression analysis, myosin Va and proteasome activator subunit 2 remained significant suggesting that these 2 proteins are key candidates for prediction of acute rejection with hemodynamic compromise within 30 days after transplantation (Figure S5).

High levels of moesin and lysine-specific demethylase 3A were associated with worse graft-related 1-year survival

Next, we investigated whether donor proteome could predict graft-related mortality. 7 of 53 recipients died due to graft-related reasons, and 6 of them during the first year, and 1 patient died 730 days after transplantation. PGD was the cause of death in 4 patients, acute rejection in 2 patients, and chronic rejection in 1 patient (Table S9). Therefore, we tested whether donor proteome could predict 1-year graft-related mortality.

In univariate analysis, we found that 5 proteins were significantly associated with 1-year graft-related mortality (Figure 4A-E). After stratification of donors using the Maxstat method, we found that high donor plasma levels of moesin and lysine-specific demethylase 3A were associated with increased graft-related 1-year mortality, while low plasma levels of D-dopachrome decarboxylase, leucine-rich alpha-2-glycoprotein, and keratin 79 were associated

Plus-minus values are mean \pm SD; values with range in parentheses are median (interquartile range). *p* values are **p*<0.05. ***p*<0.01. ****p*<0.001. During the first 24 hours, there was no difference in CKMB, lactate, and leukocytes between the donor groups. In addition, there was no difference in the function of heart transplants measured by ProBNP, and LV-EF between the donor groups after 7 days. †In the previous medical history of the heart transplant recipients, there was no peripheral vascular disease. *Acute rejection with hemodynamic compromise was diagnosed based on clinical decisions such as clinically significant decrease in left-ventricular function, increase in left-ventricular wall thickness and/or arrhythmias. The diagnose of acute rejection with hemodynamic compromise always required that the patient was treated by high dose of intravenous pulse steroids and/or antithymocyte globulin. *Acute rejection with myocyte damage is equal or more than G1Rb rejection. In this study cohort, we did not see any cases of antibody-mediated rejection within 30-days or 1-year after HTx.

with decreased graft-related 1-year mortality. In multivariate analysis of 1-year graft-related survival analyses, none of the proteins were significant (Table 4).

A summary of the possible biological role of key proteins predicting heart transplant outcome discussed further below, can be found in Table S12.

Discussion

In this study, we observed that brain-dead donors had a unique but heterogeneous proteomic signature. The changes were related to coagulation system, gluconeogenesis, and glycolysis pathways, complement, LXR/RXR activation, and production of NO and ROS in macrophages pathways. Furthermore, changes in donor plasma protein related to endothelial cell and cardiomyocyte function, inflammation, and vascular growth and arteriogenesis could predict transplant outcome suggesting their role in donor evaluation.

Despite our protein set enrichment analysis approach, making sound biological conclusions from high-dimensional MS data is still challenging.¹⁰ Therefore, data filtering is crucially important for stringent statistical analysis. However, the relevant pathophysiology of the disease process must also be considered. In this study, FDR-corrected *p* value without further filtering by log2 fold change reproduced the results of the pathophysiology of donors when compared to earlier results and our recent observations in plasma extracellular vesicle transcriptomics (SeoJeong et al., unpublished).¹¹ Based on this, we found that donor plasma showed a distinct protein profile from healthy controls, with 237 differentially expressed proteins and 6 significantly altered pathways. Out of these, 32 proteins were identified by S-Plot as the most distinguishing proteins of donors, and 10 of these proteins were enriched into 6 significantly changed pathways.

Complement and coagulation are evolutionary-related proteolytic cascades that are critical in the innate immune response to injury.^{12,13} In preclinical studies, brain death enhances complement activation and ischemia-reperfusion

injury in heart transplants.¹⁴ In our study, brain death was associated with the downregulation of complement and the upregulation of coagulation. The most significantly differentially expressed S-Plot proteins of complement and coagulation were downregulated in donors. In the comparison of donor subgroups, the complement pathway was upregulated in the Donor B group which showed more traumatic brain injury and hypertension, and in the B1 subgroup which had higher troponin and CRP within 24h and reduced cardiac function 7 days after HTx. However, lack of natural anticoagulants such as plasminogen, protein C, and antithrombin-III may lead to microvascular blood clot formation and thereby no-reflow during reperfusion of the transplant in the recipient. In addition, loss of vascular antithrombin has been linked to cardiac allograft vasculopathy and heart failure after HTx.¹⁵

Brain-dead donors showed significant downregulation of the LXR/RXR pathway. LXR/RXR are cholesterol-sensing nuclear receptors and key regulators of lipid metabolism. They may also control the innate immune response and reduce myocardial ischemia-reperfusion injury.^{16,17} The downregulated proteins of the LXR/RXR pathway were alpha-2-HS-glycoprotein, apolipoprotein A4, plasma kallikrein, kininogen 1, and paraoxonase 1. Apolipoprotein A4 attenuates platelet aggregation, thrombosis, and platelet hyperactivity, and therefore the decreased levels of apolipoprotein A4 may reflect the aggravation of prothrombotic state in brain-dead donors.¹⁸ In the kinin-kallikrein system, kininogen-1 is the precursor protein of high- and low-molecular kininogen, and bradykinin. The kinin-kallikrein system promotes blood coagulation, vasodilatation, and vascular inflammation.^{19,20} Recently, decreased levels of pre-transplant kallikrein have been shown to predict PGD after HTx.²¹ Paraoxonase-1 inhibits oxidation and apoptosis in endothelial cells and low serum levels may predispose donors to increased endothelial cell damage.²² The downregulation of LXR/RXR suggests that this pathway was possibly depleted due to inappropriate activation of inflammatory and coagulation responses in brain-dead donors.

Figure 3 Impact of donor plasma protein levels on the development of acute rejection with hemodynamic compromise within the first 30 days after heart transplantation.

(A-G) Kaplan-Meier analysis on 50 heart transplant recipients showing the curves of high (red) and low (blue) protein levels of 7 donor proteins that were significantly associated with acute rejection with hemodynamic compromise episodes within 30 days after HTx. *p* value was calculated by log-rank test and revealed that rejection-free curves were significantly different between the high and low protein level groups. (A) Proteasome subunit alpha type-6 (PSMA6): *p* value = 0.0015, (B) CRP: *p* value = 0.003, (C) CD163: *p* value = 0.024, (D) myosin Va (MYO5A): *p* value = 0.001, (E) transaldolase 1 (TALD01): *p* value = 0.0031, (F) proteasome activator subunit 2 (PSME2): *p* value = 0.0012, (G) keratin 76 (KRT76): *p* value < 0.0001. (H) Donor plasma proteomic immunological risk score was calculated based on the expression values of the 7 proteins. For high-risk level 1 point and for low-risk level zero points were given. A donor score of ≥ 1 was able to predict the risk of rejection. (Color version of figure is available online)

Under normal conditions, cardiac ATP is mainly derived from fatty acid oxidation. However, under stress conditions carbohydrates are predominantly used as an energy substrate.²³ This shift in glucose metabolism is reflected by the upregulation of the glycolysis pathway in brain-dead donors. The increased glycolysis is pivotal for anaerobic ATP production, but at the same time increased uncoupling of glycolysis and glucose oxidation may contribute to myocardial injury.^{24,25} In aerobic glucose metabolism, accumulating lipid peroxidation products are metabolized by aldose reductase via the polyol pathway protecting the heart against oxidative injury. The protective activity of aldose reductase is dependent on the generation of NO.²⁶ In our donors, we observed a downregulation of the production of NO and ROS in macrophages pathway which may result in reduced NO bioavailability, and therefore increased aldose reductase activity and less myocardial oxidative stress. Moreover, brain-dead donors showed a substantial increase in the gluconeogenesis pathway resulting in hyperglycemia and worsening of systemic inflammation.^{27–29}

Finally, we investigated whether donor plasma proteins may predict heart transplant outcomes. Interestingly, most of the proteins being correlated with any PGD or severe PGD were significantly associated with other recipient outcomes as well. Lysine-specific demethylase 3A was associated with any and severe PGD, and 1- survival, proteasome 20s subunit alpha 6 with severe PGD and acute rejection with hemodynamic compromise, moesin with severe PGD

and 1-year survival, and keratin 76 with severe PGD and acute rejection with hemodynamic compromise.

In univariate Cox regression analysis, we found that higher donor plasma levels of CD163, CRP, keratin 76, myosin Va, proteasome subunit alpha type-6, proteasome activator subunit 2, and transaldolase 1 were associated with the development of acute rejection episodes with hemodynamic compromise during the first month after transplantation. Interestingly, multivariate analysis showed that the 2 proteins myosin Va and proteasome activator subunit 2 were the best predicting proteins for acute rejection with hemodynamic compromise episodes. Myosin Va is an intracellular motor protein that plays a role in channel trafficking in cardiomyocyte membrane and has been suggested as a novel therapeutic target in cardiovascular disease.³⁰ The circulating 20s proteasome is modulated by proteasome activator (PA28) subunits such as proteasome activator subunit 2. Abnormalities of this modulation contribute to increased intimal hyperplasia and atherosclerosis.³¹

Of note is that 7 proteins found in univariate analysis on acute rejection with hemodynamic compromise were not clearly related to the top pathways observed in brain-dead donors. However, they were related to inflammation, endothelial dysfunction, and cardiovascular protein trafficking. Therefore, we hypothesize that these proteins may reflect donors' cardiovascular morbidity or endothelial and cardiomyocyte injury induced during brain death. Based on the donor plasma proteomic immunological risk score, we

Table 4 Donor Plasma Proteins as Prognostic Biomarkers for acute Rejection with Hemodynamic Compromise Within 30 Days and Graft-Related 1-Year Survival After Heart Transplantation

Clinical endpoint	Protein	Level	Maxstat Cut-off	Number	Event	Percentage	HR (CPH univariable)	HR (CPH multivariable)

Number, the group size of donors with higher protein expression and of donors with lower protein expression. Event, number of acute rejections, or number of graft-related deaths. Percentage, freedom from rejection. HR, hazard ratio; CPH, cox proportion hazard. Significant proteins in univariate COX regression analyses of acute rejection: CD163, HR 3.41, *p* value 0.034; C-reactive protein, HR 4.38, *p* value 0.007; KRT76, HR 7.31, *p* value <0.001; Myosin Va5, HR 4.7, *p* value 0.003; Proteasome subunit alpha type-6, HR 4.64, *p* value 0.004; Proteasome activator subunit 2, HR 4.65, *p* value 0.003; and Transaldolase 1, HR 4.16, *p* value 0.006. Significant proteins in multivariate COX regression analyses of acute rejection: MYO5A, HR 5.18, *p* value 0.030; and PSME2 HR 4.19, *p* value 0.029. Significant proteins in univariate COX regression analysis of survival: D-dopachrome decarboxylase, HR 5.77, *p* value 0.044; Moesin, HR 6.94, *p* value 0.018; Leucine rich alpha-2-glycoprotein 1, HR 10.4, *p* value 0.033; Lysine-specific demethylase 3A, HR 6.87, *p* value 0.026; Keratin 79, HR 10.4, *p* value 0.033. There were no significant proteins in multivariate COX regression analyses of survival.

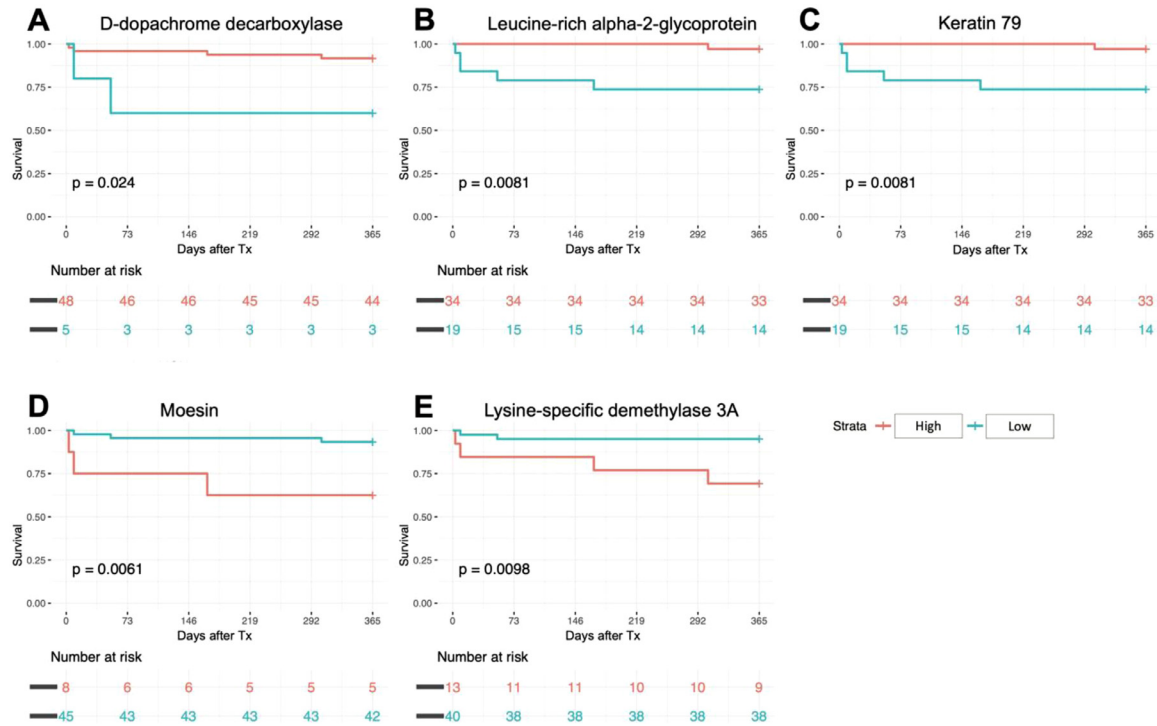

Figure 4 Impact of donor plasma protein levels on graft-related 1-year survival after heart transplantation.

Kaplan-Meier survival analysis on 50 heart transplant recipients showed that on the one hand, (A) donors with low levels of d-dopachrome decarboxylase, (B) leucine rich alpha-2-glycoprotein 1, and (C) keratin 79 had worse overall 1-year survival than donors with high levels of d-dopachrome decarboxylase (60% in low vs. 91.70% in high), leucine-rich alpha-2-glycoprotein (73.70% in low vs. 97.10% in high) and keratin 79 (73.70% in low vs. 97.10% in high). On the other hand, (D) donors with high levels of moesin and (E) lysine-specific demethylase 3A had worse overall 1-year survival than donors with low levels of moesin (93.30% in low vs. 62.50% in high) and lysine-specific demethylase 3A (95% in low vs. 69.20% in high).

showed that if any of the 7 donor proteins were upregulated, there was an increased risk of acute rejections with hemodynamic compromise within the first 30 days and that this risk increases depending on how many proteins were upregulated. These results suggest that the risk score based on these 7 proteins may be used to stratify the brain-dead organ donors.

In univariate Cox regression analysis, higher donor plasma levels of moesin and lysine-specific demethylase 3A were associated with an increased risk of graft-related 1-year mortality. Moesin, a member of the ezrin-radixin-moesin family, is expressed by vascular endothelium and has a pivotal role in vascular permeability and inflammatory responses. A recent study shows that increased serum moesin contributes to the sepsis-related endothelium damages by activating the Rock1/myosin light chain and NF- κ B signaling.³² Lysine-specific demethylase 3A promotes fibrosis in cardiomyocytes and, therefore, it has been suggested as a potential pharmacological target for cardiac hypertrophy and fibrosis.³³ Donor microvascular injury may lead to inappropriate and uncontrolled activation of the coagulation cascade and thrombin formation which may lead to the early development of tissue fibrosis in transplanted organs.³⁴ Based on these results we suggest that the high expression of these proteins may reflect the worse overall clinical status of these donors or donor hearts, which may be partly due to increased microvascular dysfunction and

cardiomyocyte damage induced by events leading to brain death.

In conclusion, we demonstrate for the first time that brain-dead donors had a unique but heterogeneous proteomic profile. We also show those donor proteins involved in endothelial dysfunction, cardiomyocyte hypoxia, and fibrosis, and vascular cell growth and arteriogenesis may play a pivotal role in graft-related outcomes. Therefore, our results suggest that systematic characterization of circulating proteins may provide a deeper understanding of the effects of donor morbidity and brain death on donor organs and identify the transplants at increased risk.

Limitations of this post-hoc analysis of a prospective, single-center study are related to the nature of the analyses and the relatively small sample size which may have an impact on data quality. The patient cohort consisted of only clinically stable multi-organ donors that were accepted for HTx. However, the median age of donors was 44 years, which is equal to the median age of heart transplant donors in Europe, compared to 31 years in North America. Depletion of the top 12 high-abundance proteins enhances the sensitivity to detect lower-abundance proteins in plasma, but it could also lead to some bias as some of the depleted proteins may have a role in the pathophysiology of brain death or prediction of the outcomes. Further mechanistic studies with a larger patient population are needed to find any biomarker or therapeutic potential of these proteins and pathways.

SUPPLEMENTAL MATERIAL

Plasma proteome of brain-dead organ donors predicts heart transplant outcome

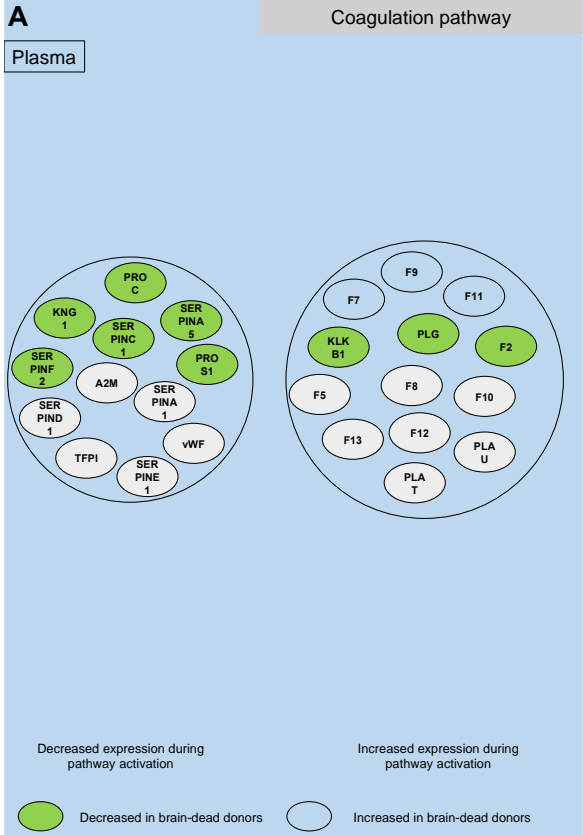

Lukac et al.

Figure S1. PCA for Donor Simvastatin treatment.

To exclude the effect of donor Simvastatin treatment on donor protein expression of 463 quantified proteins in 54 donors, PCA was performed. Examination of the PCA plot revealed that protein expression in donors did not cluster based on Simvastatin treatment. Blue: Donor Simvastatin treatment; Red: Donors without Simvastatin treatment.

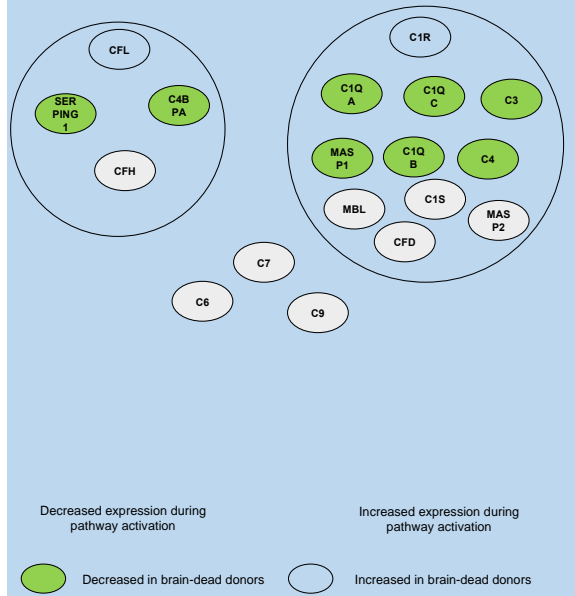

Figure S2 A-F. Top pathways and enriched plasma proteins.

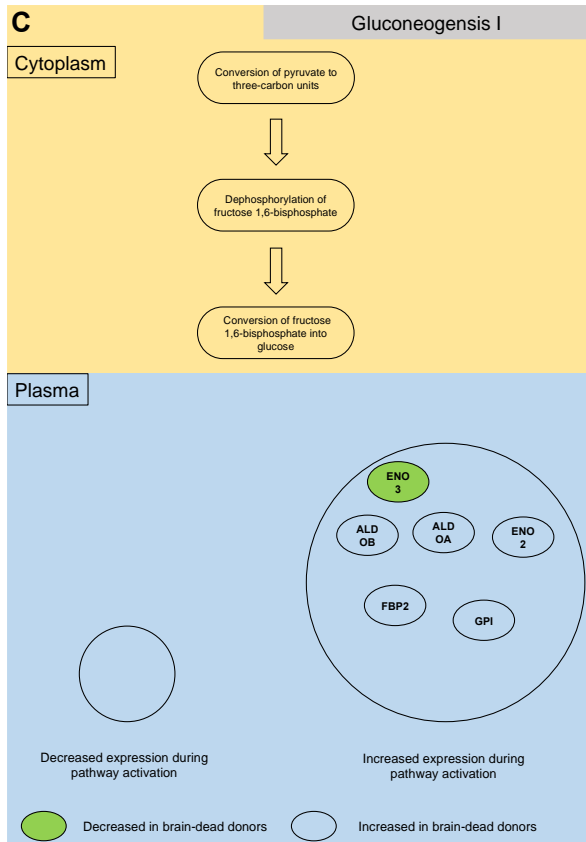

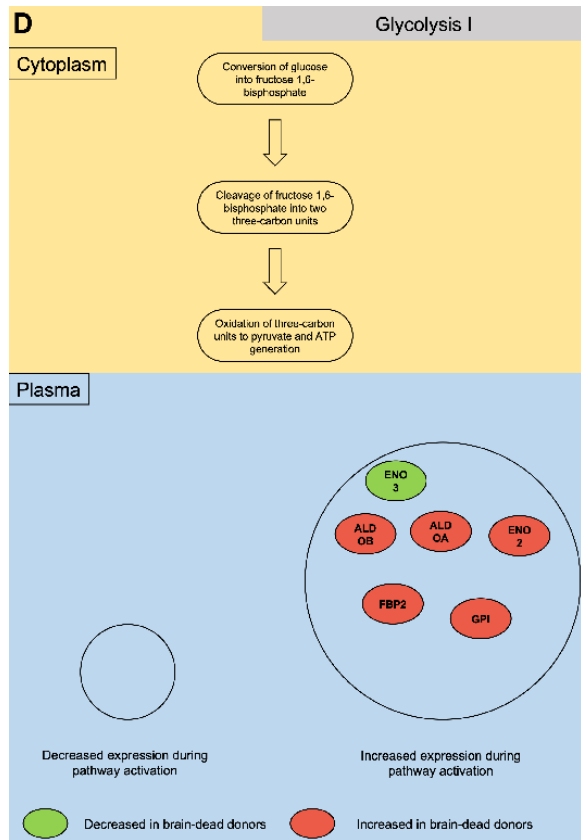

B

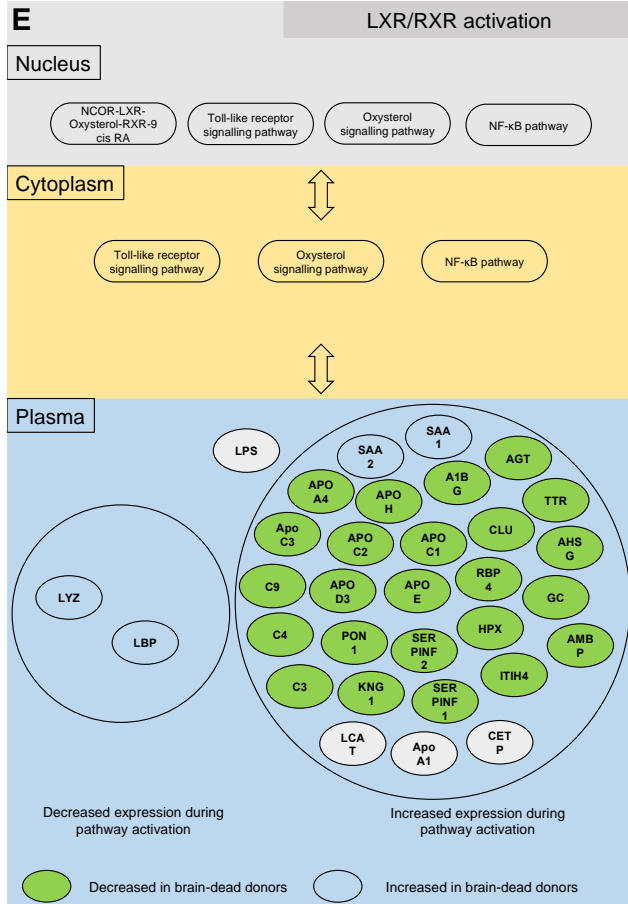

Complement pathway

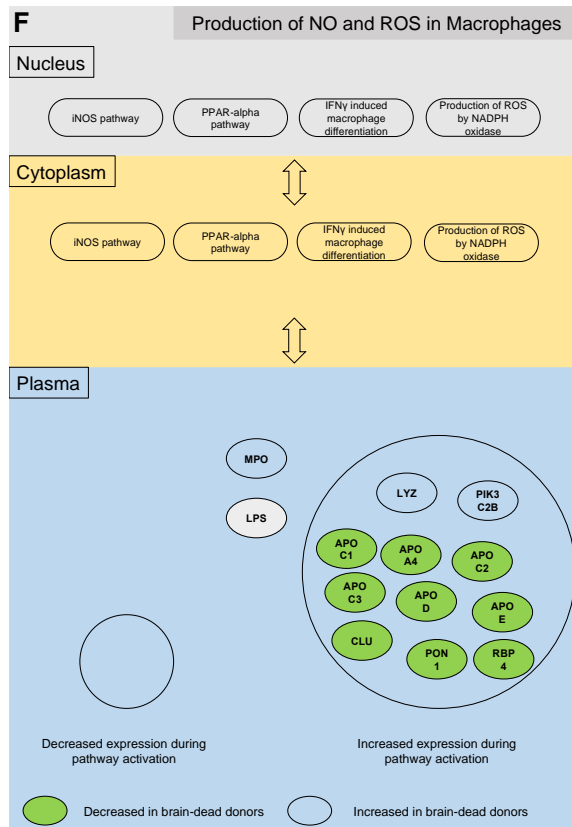

Plasma

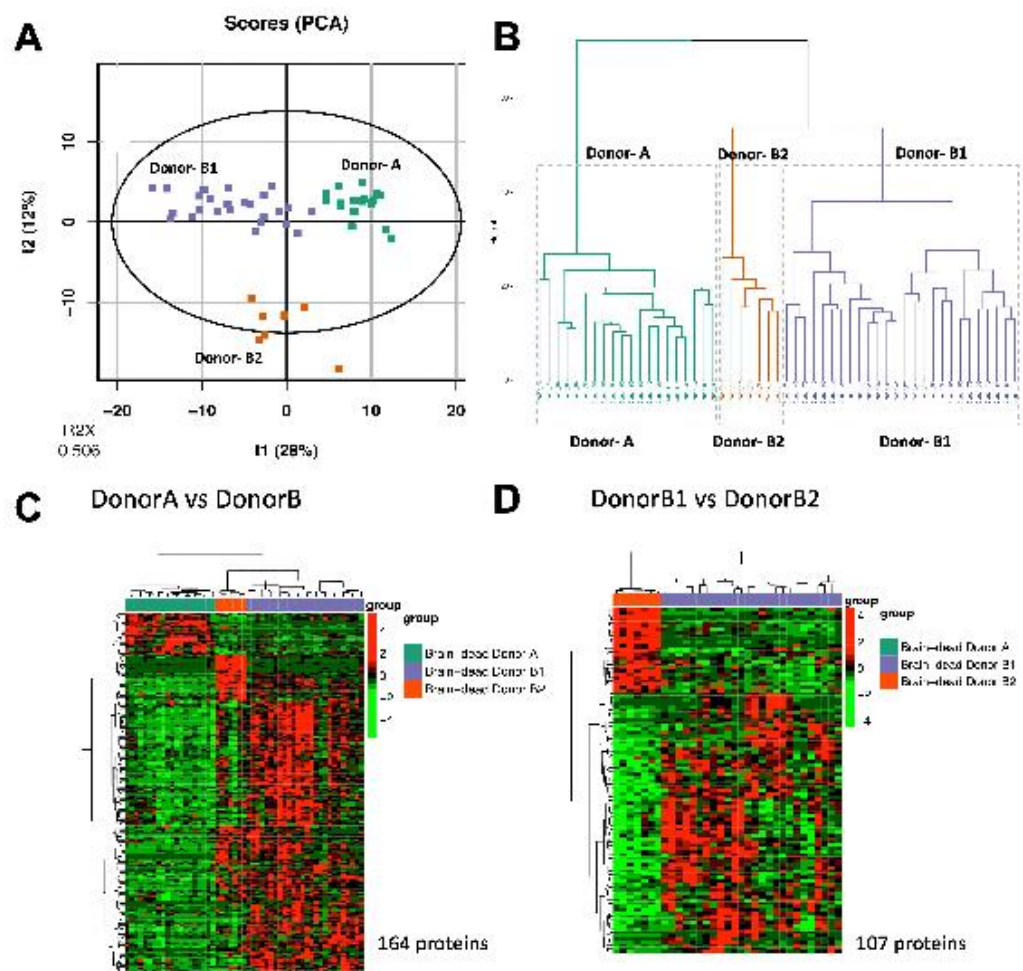

Six most significantly enriched pathways in brain-dead donors. Figure A-F pathways show key biological functions of pathways and plasma proteins that are associated with the pathways. Green: Protein with increased plasma expression in brain death and present in 237 identified proteins. Red: Protein with decreased plasma expression and present in 237 identified proteins. White: Proteins that are known to be associated with the pathway but not present among identified proteins.

Figure S3. Comparison of differentially expressed plasma proteins between subclusters of brain-dead donors.

(A) PCA analyses on 53 donor plasma samples revealed 3 subclusters, donor subcluster A, B1, and B2. **(B)** Hierarchical clustering on 53 samples presents single donor samples grouping into the 3 donor subclusters A, B1, and B2. **(C)** Univariate analysis with

SOM revealed that 164 out of 237 identified proteins were significantly different between Donor A and Donor B. **(D)** SOM analysis showed that 107 out of 237 proteins were significantly different between Donor B1 and Donor B2.

Figure S4. Donor plasma proteomic immunological risk score.

Figure S5. Multivariate Cox proportional hazards regression model for differently expressed protein levels in acute rejection with hemodynamic compromise.

Table S1. List of 32 S-Plot proteins.

Name	Protein ID	Symbol	FDR-corrected p value	Control Mean	Donor Mean	fold change	VIPscore	AUC values

All the 32 S-Plot proteins passed the cut-off $p(\text{corr}) [1] \pm 0.70$ and $p[1] \pm 0.1$. Out of 32 proteins, 3 S-Plot proteins were upregulated, while 29 proteins were downregulated in brain-dead donors. MetaboAnalyst 4.0 (<http://www.metaboanalyst.ca/>) was used for receiver operating characteristic (ROC) analysis.

Table S2. Comparison of 463 quantified proteins with two or more unique peptides identified in brain-dead donors and healthy controls.

463 quantified proteins with two or more unique peptides were compared between brain-dead donors and healthy controls. Based on the FDR-corrected p value, there were 237 differentially expressed proteins between brain-dead donors and healthy controls. These 237 significant proteins are labeled as “sign.” in the right-most column.

Table S3. Effect of log2 fold change on significantly enriched IPA pathways in brain-dead donors.

Pathway	log2fold change ND (237 proteins)	log2(fold change) ≥1 (118 proteins)	log2(fold change) ≥1.5 (66 proteins)	Identified proteins

Acute Phase Response Signaling	x	x	x	AGT,AHSG,AMBP,APOH,C1QA,C1QB,C1QC,C1R,C3, C4A/C4B,C4BPA,C9,CP,CRP,F2,HPX,ITIH2,ITIH3,ITIH 4,KLKB1,LBP,PLG,RBP4,SAA1,SAA2,SAA2SAA4,SER PINA3,SERPINF1,SERPINF2,SERPING1,TR
Agranulocyte Adhesion and Diapedesis				ACTB,CCL24,MSN,MYH10
Airway Pathology in Chronic Obstructive Pulmonary Disease	x			AMBP,APOD,C8G,MPO,RBP4
Alanine Biosynthesis II		x		GPT
Alanine Degradation III		x		GPT
Apelin Adipocyte Signaling Pathway	x	x		GSTA1,GSTM2,SOD1
Apelin Liver Signaling Pathway	x			AGT,FAS

Pathway	log2fold change ND (237 proteins)	log2(fold change) ≥1 (118 proteins)	log2(fold change) ≥1.5 (66 proteins)	Identified proteins
Arsenate Detoxification I (Glutaredoxin)			x	GSTO1
Aryl Hydrocarbon Receptor Signaling	x	x	x	ALDH1A1,ALDH1L1,CTSD,FAS,GSTA1,GSTM2,GSTO1,TRIP11
Ascorbate Recycling (Cytosolic)			x	GSTO1
Atherosclerosis Signaling	x			APOA4,APOC1,APOC2,APOC3,APOD,APOE,CLU,LYZ,PON1,RBP4
BAG2 Signaling Pathway	x			HSPA8,PSMA6,PSME2
Cell Cycle: G2/M DNA Damage Checkpoint Regulation	x			KAT2B,YWHAB,YWHAG,YWHAH,YWHAQ,YWHAZ
Clathrin-mediated Endocytosis Signaling	x			ACTB,ACTR3,APOA4,APOC1,APOC2,APOC3,APOD,APOE,CLU,F2,HSPA8,LYZ,PIK3C2B,PON1,RBP4
Coagulation System	x	x		F11,F2,F7,F9,KLKB1,KNG1,PLG,PROC,PROS1,SERPINA5,SERPINC1,SERPINF2

Pathway	log2fold change ND (237 proteins)	log2(fold change) ≥1 (118 proteins)	log2(fold change) ≥1.5 (66 proteins)	Identified proteins
Colanic Acid Building Blocks Biosynthesis	x	x	x	GPI,UGP2
Complement System	x	x		C1QA,C1QB,C1QC,C1R,C3,C4A/C4B,C4BPA,C8G,C9 ,CFI,MASP1,SERPING1
Crosstalk between Dendritic Cells and Natural Killer Cells			x	ACTB,FAS
D-glucuronate Degradation I		x	x	DCXR
Death Receptor Signaling			x	ACTB,FAS
Epithelial Adherens Junction Signaling		x	x	ACTB,ACTR3,MYH10
ERK/MAPK Signaling	x			PIK3C2B,YWHAB,YWHAG,YWHAH,YWHAQ,YWHAZ
ERK5 Signaling	x	x		YWHAB, YWHA G, YWH AH, YWHAQ, YWHAZ
Erythropoietin Signaling Pathway	x			HBD,HBE1,HBG2,HBZ,PIK3C2B
Eumelanin Biosynthesis			x	DDT

Pathway	log2fold change ND (237 proteins)	log2(fold change) ≥1 (118 proteins)	log2(fold change) ≥1.5 (66 proteins)	Identified proteins
Extrinsic Prothrombin Activation	x	x	x	F2,F7,PROC,PROS1,SERPINC1
Pathway				
Fcγ Receptor-mediated Phagocytosis in Macrophages and Monocytes			x	ACTB,ACTR3
FXR/RXR Activation	x	x	x	A1BG,AGT,AHSG,AMBP,APOA4,APOC1,APOC2,APO C3,APOD,APOE,APOH,C3,C4A/C4B,C9,CLU,GC,HPX ,ITIH4,KNG1,PON1,RBP4,SAA1,SAA2,SERPINF1,SE RPINF2,TTR
GDP-glucose Biosynthesis			x	PGM1
Glioma Invasiveness Signaling	x			PIK3C2B,PLG,TIMP1
Glucocorticoid Receptor Signaling	x	x	x	ACTB,AGT,B2M,CD163,HSPA8,KAT2B,KRT1,KRT10, KRT12,KRT13,KRT15,KRT16,KRT18,KRT4,KRT6A,KR T73,KRT76,KRT77,KRT78,KRT79,KRT86,PIK3C2B,Y WHAH

Pathway	log2fold change ND (237 proteins)	log2(fold change) ≥1 (118 proteins)	log2(fold change) ≥1.5 (66 proteins)	Identified proteins
Glucose and Glucose-1-phosphate Degradation				PGM1
Gluconeogenesis I	x	x	x	ALDOA,ALDOB,ENO2,ENO3,FBP2,GPI
Glutaryl-CoA Degradation	x			Glutaryl-CoA Degradation
Glutathione Redox Reactions I	x	x		GSTA1,GSTM2
Glutathione-mediated Detoxification	x	x		GSTA1,GSTM2,GSTO1
Glycogen Biosynthesis II (from UDP- D-Glucose)			x	UGP2
Glycogen Degradation II			x	PGM1
Glycogen Degradation III			x	PGM1
Glycolysis I	x	x	x	ALDOA,ALDOB,ENO2,ENO3,FBP2,GPI
Growth Hormone Signaling	x			IGFALS,IGFBP3,PIK3C2B
Heme Degradation		x	x	BLVRB
Hepatic Fibrosis / Hepatic Stellate Cell Activation	x		x	AGT,FAS,IGFBP3,LBP,MYH10,TIMP1

Pathway	log2fold change ND (237 proteins)	log2(fold change) ≥1 (118 proteins)	log2(fold change) ≥1.5 (66 proteins)	Identified proteins
HIPPO signaling	x			YWHAB, YWH, YWHA H, YWHAQ, YWHAZ
IGF-1 Signaling	x	x	x	IGFBP1, IGFBP2, IGFBP3, PIK3C2B, YWHAB, YWHAG, YWHAH, YWHAQ, YWHAZ
IL-10 Signaling		x	x	BLVRB, LBP
IL-6 Signaling			x	CRP, LBP
IL-12 Signaling and Production in Macrophages	x	x		APOA4, APOC1, APOC2, APOC3, APOD, APOE, CLU, LYZ, PIK3C2B, PON1, RBP4
Inhibition of ARE-Mediated mRNA Degradation Pathway	x	x		PSMA6, PSME2, YWHAB, YWHAG, YWHAH, YWHAQ, YWHAZ
Intrinsic Prothrombin Activation Pathway	x			F11, F2, F9, KLKB1, KNG1, PROC, PROS1, SERPINC1
Iron homeostasis signaling pathway	x	x		CD163, CP, HBD, HBE1, HBG2, HBZ, HPX
LPS/IL-1 Mediated Inhibition of RXR Function	x	x	x	ALDH1A1, ALDH1L1, APOC1, APOC2, APOE, FABP1, FABP5, GSTA1, GSTM2, GSTO1, LBP, SOD3

Pathway	log2fold change ND (237 proteins)	log2(fold change) ≥1 (118 proteins)	log2(fold change) ≥1.5 (66 proteins)	Identified proteins
LXR/RXR Activation	x	x	x	A1BG,AGT,AHSG,AMBP,APOA4,APOC1,APOC2,APOC3,APOD,APOE,APOH,C3,C4A/C4B,C9,CLU,GC,HPX,ITIH4,KNG1,LBP,LYZ,PON1,RBP4,SAA1,SAA2,SERPINF1,SERPINF2,TTR
Maturity Onset Diabetes of Young (MODY) Signaling	x	x		ALDOB,APOA4,APOC1,APOC2,APOC3,APOD,APOE,APOH,APOL3,FABP1
Mechanisms of Viral Exit from Host Cells		x	x	ACTB,CHMP6
Melatonin Degradation III		x		MPO
MSP-RON Signaling In Cancer Cells Pathway	x			F11,HGFAC,KLKB1,PIK3C2B,YWHAB,YWHAG,YWHAH,YWHAQ,YWHAZ
MSP-RON Signaling Pathway	x			ACTB,F11,KLKB1,PIK3C2B
Neuroprotective Role of THOP1 in Alzheimer's Disease	x		x	AGT,C1R,F11,F7,HGFAC,KNG1,MASP1,PLG,SERPINA3

Pathway	log2fold change ND (237 proteins)	log2(fold change) ≥1 (118 proteins)	log2(fold change) ≥1.5 (66 proteins)	Identified proteins
NRF2-mediated Oxidative Stress Response	x	x	x	ACTB,GSTA1,GSTM2,GSTO1,PIK3C2B,PRDX1,SOD1,SOD3
p53 Signaling	x			FAS,KAT2B,PIK3C2B,THBS1
p70S6K Signaling	x			AGT,F2,PIK3C2B,YWHAB,YWHAG,YWHAH,YWHAQ,YWHAZ
PEDF Signaling	x			FAS,PIK3C2B,SERPINF1
Pentose Phosphate Pathway	x	x		TALDO1,TKT
Pentose Phosphate Pathway (Non-oxidative Branch)	x	x	x	TALDO1,TKT
PFKFB4 Signaling Pathway	x	x		FBP2,GPI,TKT
Phagosome Maturation	x			B2M,CTSD,MPO,PRDX1,PRDX2
PI3K/AKT Signaling	x			YWHA B, YW H AG, Y WHAH,YWHAQ,YWHAZ
Production of Nitric Oxide and Reactive Oxygen Species in Macrophages	x	x		APOA4,APOC1,APOC2,APOC3,APOD,APOE,CLU,LYZ,MPO,PIK3C2B,PON1,RBP4

Pathway	log2fold change ND (237 proteins)	log2(fold change) ≥1 (118 proteins)	log2(fold change) ≥1.5 (66 proteins)	Identified proteins
PXR/RXR Activation	x	x	x	ALDH1A1,GSTA1,GSTM2,IGFBP1
Rac Signaling	x			ACTR3,MCF2L,PIK3C2B,PIP4K2C
RAR Activation	x			ACTB,ALDH1A1,IGFBP3,KAT2B,RBP4
Regulation of Actin-based Motility by Rho		x	x	ACTB,ACTR3,PIP4K2C
Remodeling of Epithelial Adherens Junctions		x	x	ACTB,ACTR3
RhoA Signaling	x	x	x	ACTB,ACTR3,MSN,PIP4K2C
RhoGDI Signaling		x	x	ACTB,ACTR3,MSN,MYH10,PIP4K2C
Role of Pattern Recognition Receptors in Recognition of Bacteria and Viruses	x			C1QA,C1QB,C1QC,C3,PIK3C2B,PTX3
Sucrose Degradation V (Mammalian)	x	x	x	ALDOA,ALDOB,TKFC
Superoxide Radicals Degradation	x	x	x	SOD1,SOD3
Thymine Degradation		x	x	UPB1

Pathway	log2fold change ND (237 proteins)	log2(fold change) ≥1 (118 proteins)	log2(fold change) ≥1.5 (66 proteins)	Identified proteins
Tumoricidal Function of Hepatic Natural KillCellsIIs	x			FAS,LYVE1
Tyrosine Degradation I			x	HPD
Uracil Degradation II (Reductive)		x	x	UPB1
Urea Cycle	x			ASL,CPS1
Vitamin-C Transport	x	x	x	GSTO1,LRRC8C
Xenobiotic Metabolism AHR Signaling Pathway	x	x	x	ALDH1A1,ALDH1L1,GSTA1,GSTM2,GSTO1,PON1
Xenobiotic Metabolism CAR Signaling Pathway	x	x	x	ALDH1A1,ALDH1L1,GSTA1,GSTM2,GSTO1,SOD3
Xenobiotic Metabolism General Signaling Pathway	x	x		GSTA1,GSTM2,GSTO1,PIK3C2B
Xenobiotic Metabolism PXR Signaling Pathway	x	x	x	ALDH1A1,ALDH1L1,GSTA1,GSTM2,GSTO1

Pathway	log2fold change ND (237 proteins)	log2(fold change) ≥1 (118 proteins)	log2(fold change) ≥1.5 (66 proteins)	Identified proteins
Xenobiotic Metabolism Signaling	x	x	x	ALDH1A1,ALDH1L1,GSTA1,GSTM2,GSTO1,PIK3C2B, SOD3

IPA enrichment analysis pathways with a $-\log(p \text{ value})$ of >1.3 ($p \text{ value} <0.05$) without taking z-score into account. Identified proteins enriched into significant pathways are presented.

Table S4. List of enriched pathways comparing Donor A and Donor B.

Ingenuity Canonical Pathways	$-\log(p \text{ value})$	z-score	Identified proteins
Acute Phase Response Signaling	26	-1,265	AGT,AMBP,APOH,C1QA,C1QB,C1QC,C1R,C3,C4A/C4B,C4BPA,C9,C10A,C10B,C10C,CRP,F2,HPX,ITIH2,ITIH4,KLKB1,PLG,RBP4,SAA1,SAA2,SERPINA3,SERPINF2,SERPING1,TTR
LXR/RXR Activation	21,3	-3,13	AGT,AMBP,APOA4,APOC1,APOD,APOE,APOH,C3,C4A/C4B,C9,HPX,I

Ingenuity Canonical Pathways	-log(p value)	z-score	Identified proteins
			TIH4,KNG1,LYZ,PON1,RBP4,SAA1, SAA2,SERPINF2,TTR
FXR/RXR Activation	19,6	NA	AGT,AMBP,APOA4,APOC1,APOD, APOE,APOH,C3,C4A/C4B,C9,HPX,I TIH4,KNG1,PON1,RBP4,SAA1,SAA 2,SERPINF2,TTR
Complement System	16,9	-1,265	C1QA,C1QB,C1QC,C1R,C3,C4A/C 4B,C4BPA,C8G,C9,CFI,MASP1,SE RPING1
Coagulation System	10,1	0	F2,F9,KLKB1,KNG1,PLG,PROS1,S ERPINC1,SERPINF2
Intrinsic Prothrombin Activation Pathway	6,37	-0,447	F2,F9,KLKB1,KNG1,PROS1,SERPI NC1
Glycolysis I	6,06	-2,236	ALDOA,ENO2,ENO3,FBP2,GPI
Gluconeogenesis I	6,06	-2,236	ALDOA,ENO2,ENO3,FBP2,GPI
Clathrin-mediated Endocytosis Signaling	6,01	NA	ACTR3,APOA4,APOC1,APOD,APO E,F2,LYZ,PIK3C2B,PON1,RBP4

Ingenuity Canonical Pathways	-log(p value)	z-score	Identified proteins
Maturity Onset Diabetes of Young (MODY) Signaling	5,94	NA	APOA4,APOC1,APOD,APOE,APOH,APOL3,FABP1
IL-12 Signaling and Production in Macrophages	5,32	NA	APOA4,APOC1,APOD,APOE,LYZ,PIK3C2B,PON1,RBP4
Production of Nitric Oxide and Reactive Oxygen Species in Macrophages	5,12	-2,121	APOA4,APOC1,APOD,APOE,LYZ,MPO,PIK3C2B,PON1,RBP4
Glucocorticoid Receptor Signaling	4,89	NA	AGT,B2M,CD163,KAT2B,KRT1,KRT10,KRT15,KRT16,KRT18,KRT4,KRT73,KRT76,KRT77,KRT78,PIK3C2B

Plus-minus values are mean ±SD; values with range in parentheses are median (interquartile range). CMV indicates cytomegalovirus; HDL, high-density lipoprotein; LDL, low-density lipoprotein; ROSC, return of spontaneous circulation; Tx, transplantation. P-values are marked as asterisks (*P<0.05. **P<0.01. ***P<0.001).

Table S12. The possible biological role of key proteins predicting heart transplant outcomes.

	Protein	Expression level in donors with worse heart transplant outcome	Possible biological role in cardiac pathophysiology
Any PGD	Beta-ureidopropionase	High	<i>Unknown</i>
	Nicolin 1	Low	<i>Unknown</i>
	Lysine-specific demethylase 3A	High	Fibrosis of cardiomyocytes
	Insulin-like growth factor binding protein 2	Low	Angiogenesis and antiapoptosis
	Retinol-binding protein 4	Low	Insulin resistance and cardiomyocyte hypertrophy
Severe PGD	Proteasome subunit alpha type-6	High	Angiogenesis and arteriogenesis
	Moesin	High	Endothelial dysfunction
	Apolipoprotein L3	High	Angiogenesis and endothelial dysfunction
	Eomesodermin	Low	Leukocyte activation
Acute rejection with hemodynamic compromise	Keratin 76	High	Hypoxia in cardiomyocytes
	CD163	High	Leukocyte activation
	CRP	High	Endothelial dysfunction
	Keratin 76	High	Hypoxia in cardiomyocytes
	Myosin Va	High	Channel trafficking in cardiomyocytes
	Proteasome subunit alpha type-6	High	Angiogenesis and arteriogenesis

	Protein	Expression level in donors with worse heart transplant outcome	Possible biological role in cardiac pathophysiology
within 30 days	Proteasome activator subunit 2	High	Angiogenesis and arteriogenesis
	Transaldolase 1	High	Endothelial dysfunction and oxidative stress
1-year survival	D-dopachrome decarboxylase	Low	Fibrosis and angiogenesis
	Leucine-rich alpha-2-glycoprotein 1	Low	Angiogenesis and cardiac remodeling
	Lysine-specific demethylase 3A	High	Fibrosis of cardiomyocytes
	Moesin	High	Endothelial dysfunction
	Keratin 79	Low	<i>Unknown</i>

METHODS

Plasma sample processing and trypsin digestion

Plasma samples were drawn into 10ml heparin tubes coated with lithium and centrifuged at 1600xg at RT for 10 min. Subsequently, samples were cooled down to -20 °C and moved to -80 °C until further processing.¹ The analysis of low-abundant proteins is complicated by the presence of high concentrations of proteins such as albumin and IgG. Therefore, the removal of these proteins is essential for the study.

The protein amount of the depleted plasma was measured with BRADFORD MX reagent (EXPEDION) and an equal amount of protein per sample was dried and resuspended in 50 mM Tris buffer containing 6 M urea (pH 7.8). Dithiothreitol was added to a final concentration of 10 mM and samples were shaken at RT for 1 hour. Iodoacetamide was added to a final concentration of 40 mM and samples were shaken at RT for 1 hour. Dithiothreitol (40 mM) was used to quench excess iodoacetamide at RT for 1 hour. Trypsin was added to the protein mixtures at a trypsin:protein ratio by weight of 1:50 and the samples were incubated at 37 °C overnight. For trypsin digestion one missed cleavage was allowed. The resulting tryptic peptides were cleaned with C18 spin columns. Tryptic peptides were desalted and isolated by C18 spin columns (Pierce, ThermoFisher). Peptides were dissolved to achieve a final

concentration of 1.4µg/4µL in 0.1% formic acid. 12.5 fmol/µL of Hi3 spike-in standard peptides (Waters, MA, USA) were included to enable the quantification. Auto error tolerances for fragment and precursor were used. Minimum one ion fragment per peptide, minimum three fragments per protein, and minimum one peptide per protein were marked as “required” for ion matching. Peptide abundances were normalized with Hi3 spiked standard and relative quantitation was performed with the non-conflicting peptides found.

Nano Ultra Performance Liquid Chromatography and quantification of Label-Free Ultra-definition mass spectrometry (UPLC-MS/MS)

We performed UPLC-MS/MS as described.² Samples of 4 µL (equivalent to ~1.4µg total protein) were injected into a nanoAcquity UPLC-system (Waters Corporation, MA, USA). As a separating device before the mass spectrometer, we used TRIZAIC nanoTile 85µm x 100 mm HSS-T3u wTRAP. Buffers were made from UPLC-grade chemicals (Sigma-Aldrich, MO, USA). Data was acquired in a data-independent acquisition mode (UDMSE) with a Synapt G2-S HDMS (Waters Corporation, MA, USA) in resolution mode. Progenesis QI for proteomics software (Nonlinear Dynamics, Newcastle, UK) was used for protein identification with an FDR of less than 2%. The peptide identification was done against Uniprot human FASTA sequences (UniprotKB Release 2015_09, 20205 sequence entries) which included ClpB protein sequence (CLPB_ECOLI (P63285)) for label-free quantification. The quantified protein amounts equaled the total protein contents of the analyzed samples.

Univariate and multivariate analysis for finding differentially expressed proteins

Multivariate analysis was carried out with OPLS-DA modeling to further discriminate between the 2 groups. OPLS-DA modeling allows us to find variables that are driving the separation between 2 groups and proteins associated with it. ROC analysis generates a plot of the true positive rate against the false-positive rate. The area under the ROC curve (AUC) is an objective and statistically valid technique for biomarker performance evaluation and allows interpretation for disease classification from healthy subjects.

Enrichment pathway analysis on differentially expressed proteins in brain-dead donors

QIAGEN Ingenuity Pathway Analysis (IPA; Ingenuity Systems, Redwood City, CA, USA) is a commercially available web-based bioinformatics application. IPA implements the manually expert-curated QIAGEN Knowledge Base which retrieves relevant scientific and clinical information from the literature and public databases. In pathway analysis, IPA identifies significant pathways by calculating a $-\log(p \text{ value})$. A $-\log(p \text{ value})$ value of >1.3 is corresponding to a p value of <0.05 and is generally considered as a cut-off for significant pathways. Moreover, IPA calculates an activation z-score. The z-score makes predictions about potential inhibition or activation of identified pathways.

To interrogate the biological importance of S-Plot proteins, proteins were separately matched to the top biological pathways with a p value of <0.001 and an absolute value of z-score greater than 1, and to the information retrieved from literature research. By

summarizing the protein-specific characteristics, we filtered S-Plot proteins that were taking part in the most important biological pathways of protein set enrichment analyses, and out of S-Plot proteins, these proteins and their associated pathways were further discussed.

Clinical outcome analysis

The diagnostic criteria for PGD were established in a consensus statement by ISHLT in 2014.³ Correlation analysis provides a correlation coefficient (r-value) which ranges from 0 to 1. The diagnosis and treatment of acute rejection with hemodynamic compromise were based on clinical decisions such as a clinically significant decrease in ventricular function increase, increase in ventricular wall thickness, and/or arrhythmias. The diagnose of acute rejection with hemodynamic compromise always required treatment with high dose of intravenous pulse steroids, and/or anti-thymocyte globulin. We did not consider any other acute rejections equal to or greater than grade 2R based on ISHLT criteria or any other endpoints for acute rejection due to the low incidence of these rejections in our study cohort.⁴

Statistical analysis of demographics

In statistical analysis of baseline demographic and clinical characteristics, we used the Kolmogorov-Smirnov test to determine the normality of distributions. For 2-group comparisons, the independent samples t-test or Mann-Whitney U-test was used for parametric

and non-parametric variables, respectively. For categorical comparisons, Fisher's exact test was applied. $P < 0.05$ was considered statistically significant.

Results

Study population and demographic data

The final study population consisted of 53 multi-organ donors for HTx, and 23 age and sex-matched healthy blood donors. The median age of the donors was 44 years (interquartile range: 33-51), and 10 (18.9%) were female. In healthy controls, the median age was 46 years (37-54), and 6 (21.1%) were female. Causes of donor brain death were intracranial hemorrhage (49.1%), traumatic brain injury (35.8%), cerebral infarction (11.3%), and other (3.8%). The mean time between the declaration of brain death and organ procurement was 14.9 ± 4 hours, an approximate time for plasma collection for proteomics (**Table 1**).

Specific treatment for acute rejection with hemodynamic compromise

Out of 16 recipients with acute rejection with hemodynamic compromise, 9 recipients received methylprednisolone 500mg/day for 3 days, 2 patients received methylprednisolone 500mg/day for 2 days, and 1 patient methylprednisolone 250mg/day for 3 days. 3

patients received first methylprednisolone 500mg/day for 3 days and then anti-thymocyte globulin once daily for 3 days. One patient received only anti-thymocyte globulin once daily for 3 days.

Proteome profile discriminated 3 subclusters within brain-dead donors

We carried out separate PCA analysis and hierarchical clustering including only brain-dead donors. This analysis confirmed that there were 2 main clusters of donors (Donor A and Donor B), and the Donor B cluster was grouped into 2 subclusters Donor B1 and B2 (**Figure S3A, B**). In donor characteristics, cerebral infarction as a donor cause of death was significantly more prominent in Donor A group, while traumatic brain injury was more prominent in the Donor B group. All the donors with hypertension in their medical history (18.2%) belonged to the Donor B1 group. Donor B2 subcluster had significantly reduced levels of thrombocytes and plasma LDL when compared to the Donor B1 group. When comparing the recipient outcomes between Donor A and Donor B groups, none of the recipients from Donor A was treated with LVAD, whereas 21.2% of recipients from Donor B were bridged with LVAD. However, transplants from the Donor B2 group showed a better left-ventricle ejection fraction at 7 days, lower hsTnI and hsTnT at 6h, 12h, and 24h, and lower high sensitivity CRP at 24h after transplantation (**Table 1, Table 3**). Univariate analysis on the 3 subclusters of donors showed that out of 237 proteins, 164 proteins were significantly different between Donor A and Donor B (**Figure S3C**), and 107 proteins significantly differed between Donor B1 and Donor B2 (**Figure 3D**). Pathway enrichment analysis on differentially expressed

proteins between Donor A and B subcluster (N=164), and Donor B1 and B2 subclusters (N=107) showed that most of the enriched pathways were overlapping between the donor subclusters (**Table S4 and S5**).

DISCUSSION

Generally, acute brain injury results in systemic acute phase response, a coordinated series of neuroendocrinological, physiological, and metabolic changes initiated after tissue injury as a repair and regeneration process. Out of 31 identified proteins belonging to acute phase response signaling, 23 downregulated proteins belonged to complement and coagulation pathways. Considering the nature of brain injury and brain death, it is possible that these proteins were consumed during the activation of these pathways during these incidents. Even though the acute phase response signaling pathway did not show an activation pattern based on z-score, our results suggest that acute phase response was present in brain-dead donors.

Beta-ureidopropionase, Nicotin 1, insulin-like growth factor binding protein 2, and retinol-binding protein 4 were correlated with any PGD grade. Beta-ureidopropionase functions as an enzyme in pyrimidine graduation.⁵ Pyrimidines are important regulators of the central nervous system and alterations of pyrimidine are linked to neurological disorders.⁶ However, the potential function of beta-

ureidopropionase in brain-dead organ donors remains to be elucidated. Nicotin 1 may be mostly expressed by the liver while expression levels depend on the metabolic state of the liver.⁷ However, more research is warranted to elucidate the biological function of Nicotin 1. Insulin-like growth factor binding protein 2 has been suggested as a strong diagnostic and prognostic biomarker for heart failure which may have higher accuracy than brain natriuretic peptide.⁸ Under hypoxic conditions and oxidative stress, insulin-like growth factor binding protein 2 enhances VEGF expression which mediates anti-apoptosis and angiogenesis.^{9,10} In lung transplant recipients, pretransplant VEGF levels predict primary graft dysfunction.¹¹ Retinol-binding protein 4 a has been suggested as a prognostic biomarker for heart failure as well.¹² Retinol-binding protein 4 activates the pro-inflammatory TLR4/MyD88 pathway by which it promotes insulin resistance and hypertrophy in cardiomyocytes.¹³

Moreover, apolipoprotein L3 and eomesodermin were correlated to severe PGD. Apolipoprotein L3 modulates MAPK and FAK signaling pathways in endothelial cells and contributes to inflammation-mediated angiogenesis and endothelial dysfunction.¹⁴ Eomesodermin, also known as eomes, is involved in CD4(+) T-cell differentiation, and CD4(+) eomes T-cells accumulate in inflamed tissues of patients with proinflammatory diseases.^{15,16,17} In acute ischemia-reperfusion injury, CD4(+) T-cells mediate the infiltration of neutrophils and chemokine production.¹⁸ Therefore, we hypothesize that eomes may play a role in CD4(+) mediated ischemia-reperfusion injury which is inherently connected to the development of primary graft dysfunction.

Transaldolase 1 was significantly associated with acute rejection with hemodynamic compromise. Transaldolase 1 is a key enzyme of the nonoxidative pentose-phosphate pathway. The pentose-phosphate pathway plays a pivotal role in cardiac anaerobic glucose metabolism, and pathway activity is enhanced by hyperglycemia and aggravates endothelial dysfunction and oxidative stress in failing hearts.^{19,20} CD163 is a high-affinity scavenger receptor for the hemoglobin-haptoglobin complex but also a macrophage activation marker.²¹ CD163 has been introduced as an immune-related biomarker for the severity of heart failure.²² CRP may affect NO bioavailability and induce endothelial dysfunction.²³ High CRP levels in brain-dead donors are associated with worse short-term outcomes in kidney transplantation.²⁴ Increased Keratin 76 expression in fetal cardiomyocytes may be induced by endothelin-1 during hypoxia-induced remodeling.²⁵

In 1-year survival analysis, D-dopachrome decarboxylase, leucine-rich alpha-2-glycoprotein 1, and keratin 79 were identified as statistically significant proteins. D-dopachrome decarboxylase, also known as macrophage inhibitory factor-2 (MIF-2), is involved in the modulation of immune response and has been recently introduced as a novel inflammatory mediator in CNS pathophysiology.²⁶ In experimental studies, DDT in cardiomyocytes mediates anti-fibrotic and anti-angiogenic effects and protects against heart failure. Patients with heart failure undergoing heart transplantation showed decreased DDT expression levels in cardiomyocytes.²⁷ Furthermore, DDT has been shown to protect the heart against ischemia-reperfusion injury-induced injury and contractile dysfunction.²⁸ Leucine-rich alpha-2-glycoprotein 1 is secreted also by activated neutrophils and promotes angiogenesis by modulating

endothelial TGF β 1 signaling and attenuates adverse cardiac remodeling.^{29, 30, 31} Keratin 79 is a filament protein in endothelial cells.³² Despite its statistical significance, the biological association between Keratin 79 and pathophysiology in heart transplant recipients remains unclear at this point.
